QUERY OBFUSCATION WITH EMBEDDING-OPTIMIZED NOISE (EON): A REPRESENTATIONAL BLINDSPOT IN AGENTIC RETRIEVAL

Anonymous authors
Paper under double-blind review

ABSTRACT

In modern agentic and semantic retrieval systems, dense embedding models increasingly determine which intent, tool, document, memory, or image to retrieve for a query. We identify a representational failure mode in this pipeline: a meaningful query can be replaced by visibly nonsemantic content while preserving much of its retrieval outcome, even when the candidate bank is hidden from the optimizer. We introduce *Embedding-Optimized Noise (EON)*, constructed using only the natural query representation, without access to candidate embeddings, relevance labels, rankings, retrieval feedback, or guardrail decisions. Despite this corpus-blind objective, EONs frequently preserve intent and tool routing, benchmark document search, episodic agent-memory retrieval, and cross-modal search across multiple dense embedding families. Crucially, this disconnect carries serious security implications: for malicious queries, an EON can reliably evade input guardrails that block the natural query, executing the intended safety-sensitive retrieval undetected. Through the geometry of the embedding space, we then characterize how query-level representation matching can reliably maintain subsequent retrieval outcomes over candidates unseen during optimization. Together, these findings expose a fundamental phenomenon across dual encoders that we call BLINDSPOT, where systems remain operationally blind to nonsemantic artifacts while reliably retrieving real, consequential content.

1 INTRODUCTION

Modern AI systems increasingly rely on dense embeddings not only for semantic retrieval, but across agentic pipelines where retrieved documents, memories, tools, and multimodal content can shape system behavior. Dual encoders are especially well suited to this role because candidate representations can be precomputed and retrieved efficiently at scale (Reimers & Gurevych, 2019; Karpukhin et al., 2020). A query representation may retrieve documents for retrieval-augmented generation (Lewis et al., 2020), match multimodal content (Radford et al., 2021), recover episodic memory (Zhang et al., 2026b), or identify relevant tools (Molfetta et al., 2025; Sengupta et al., 2026). In these settings, the query vector is therefore more than a semantic representation: its geometry determines which evidence, memories, and capabilities are brought into the model's context, with direct consequences for subsequent behavior.

This design relies on a close relationship between representation and meaning. Learned embedding spaces, however, need not preserve human semantic judgments. Semantically unrelated texts can collide in representation space (Song et al., 2020), and visually mismatched adversarial queries can produce retrieval results similar to those of a target image (Tolias et al., 2019). Other work manipulates queries toward known retrieval targets (Song et al., 2025), or modifies the corpus, memory, or cache being searched (Zhong et al., 2023; Chen et al., 2024b; Wu et al., 2026). We study a more information-restricted setting: can a visibly nonsemantic artifact act as an operational proxy for a natural query, preserving its retrieval behavior without observing the candidate bank or the entity retrieved by that query?

We call such nonsemantic proxies *Embedding-Optimized Noise* (EON). Given a natural query, we construct an EON using a simple gradient-free greedy search that modifies a nonsemantic artifact

If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

Figure 1: **Representative examples of nonsemantic query proxies bypassing guardrails while preserving blocked retrieval outcomes.** Rows show text-to-text retrieval on PKU-SafeRLHF with Qwen3-Embedding-0.6B, text-to-image retrieval on T2I-RiskyPrompt with CLIP, and image-to-image retrieval on T2I-RiskyPrompt with DINOv3. In every case, query guardrail blocks natural safety-sensitive query q but allows its visibly nonsemantic EON q^*. Although q^* is optimized using only the natural query representation and never observes the candidate bank, both q and q^* retrieve the identical top-ranked outcome A_1. Text queries are evaluated with Qwen3Guard-8B and image queries with ShieldGemma-2-4B. This operational mismatch between surface-level safety and embedding-based retrieval is the BLINDSPOT. See Table 21 and 22 for more qualitative examples.

to make its embedding as close as possible to the natural query representation. The optimizer never observes candidate identities or embeddings, relevance labels, rankings, retrieval scores, or guardrail

decisions. It therefore does not know which intent, tool, document, memory, response, or image the natural query retrieves; its only objective is to reproduce the natural query representation.

Despite these severe constraints, optimized EONs frequently inherit the retrieval outcome of their source queries. We observe substantial natural-query outcome preservation across intent routing, tool selection, full-corpus document retrieval, episodic agent memory, text-to-image retrieval, and image-to-image retrieval, spanning multiple independently trained dense embedding families. Notably, this preservation also appears on LongMemEval and MemBench (Wu et al., 2025; Tan et al., 2025), where each query is evaluated against a different memory pool. This rules out adaptation to a single fixed retrieval index and strengthens the corpus-blind interpretation. Matched random noise controls rarely preserve natural selections, confirming that these artifacts are non-trivial, and systematically increasing query-EON cosine similarity yields higher candidate preservation.

This representational gap creates an immediate vulnerability at the boundary between query moderation and retrieval. Because EONs look like harmless nonsemantic noise, they can easily slip past query guardrails designed to catch overt malicious intent (Inan et al., 2023; Han et al., 2024). Our guardrail evaluations reveal that this is precisely what happens, with independent safety classifiers frequently permitting EONs, often at rates comparable to matched random strings, while reliably intercepting the corresponding natural malicious requests. The result is a striking security loophole: an attacker can bypass front-line moderation with an artifact that appears entirely benign, yet still preserve the safety-sensitive retrieval outcome of the blocked query.

We call this phenomenon BLINDSPOT, as our findings demonstrate that dense dual encoders across modern retrieval architectures are operationally blind to the linguistic validity of an incoming query. Because these representations mediate retrieval across modern semantic and agentic pipelines, the mismatch can propagate directly into subsequent system behavior (An et al., 2025; Chen et al., 2024b). Geometrically, query-level representation matching constrains score changes over unseen candidates, allowing retrieval outcomes to remain stable without access to the candidate bank.

In a nutshell, in this study:

- We introduce **corpus-blind query proxying**, where we construct a nonsemantic proxy by matching only the representation of a natural query, without gradients, candidate-bank access, retrieval feedback, or guardrail feedback.
- We show that EONs can **preserve the retrieval behavior of natural queries** across intent routing, tool selection, document retrieval, agent memory, cross-modal retrieval, and image retrieval, even when the relevant candidate bank is never observed during optimization.
- We demonstrate a **joint guardrail–retrieval failure**: the same EON can pass an independent semantic guardrail that rejects the natural malicious query while still preserving its safety-sensitive retrieval outcome.
- We connect this behavior to **the geometry and architecture of retrieval**: closer query representations generally preserve retrieval more strongly, exact target similarity need not be maintained.

2 RELATED WORK

2.1 DENSE RETRIEVAL IN FOUNDATION-MODEL SYSTEMS

Dense retrieval maps queries and candidates into a shared representation space, enabling large candidate collections to be searched efficiently using vector similarity (Reimers & Gurevych, 2019; Karpukhin et al., 2020). This abstraction has expanded beyond conventional document search. Multimodal encoders such as CLIP support retrieval across text and images (Radford et al., 2021), while retrieval-augmented generation uses external retrieval to supply foundation models with information beyond their parametric knowledge (Lewis et al., 2020). Modern agents extend the same idea to action selection: retrieval is used to identify relevant tools from large inventories (Shi et al., 2025; Molfetta et al., 2025; Sengupta et al., 2026) and to recover information from external memory (Zhang et al., 2026b). Retrieval can therefore determine not only what information is returned, but also what information or capability becomes available to subsequent model reasoning.

A common design uses a single vector for each query and candidate, allowing candidate representations to be precomputed and searched efficiently. Late-interaction methods such as ColBERTv2 instead retain token-level representations and defer part of the matching computation until retrieval time (Santhanam et al., 2022). This distinction is relevant to our setting because the blindspot phenomenon targets the query representation itself: when a single vector mediates the retrieval decision, reproducing that vector may reproduce behavior over many possible candidate banks.

2.2 Representation Mismatch and Adversarial Queries

Neural representation spaces need not align perfectly with human semantic judgments. Song et al. (2020) demonstrated semantic collisions in which unrelated texts are mapped to similar representations, establishing that embedding proximity can be manipulated independently of apparent meaning. Related work has exploited the query side of retrieval directly. In image retrieval, Tolias et al. (2019) construct visually unrelated adversarial queries that produce retrieval results similar to those of a target image, while subsequent work studies query-efficient black-box attacks against image-retrieval systems (Li et al., 2021). Textual RAG systems have likewise been attacked by modifying queries so that a chosen document enters the retrieved context (Song et al., 2025).

These works make clear that query-side adversarial manipulation itself is not new. Our setting differs in what is optimized and what information is available. EONs are not optimized to retrieve, suppress, or rerank any known candidate. Instead, they are optimized only to reproduce the representation of a natural query and are evaluated afterward against a candidate bank that was absent from the optimization loop. The resulting question is whether a nonsemantic proxy can inherit the retrieval behavior of an arbitrary meaningful query without knowing what that query retrieves.

2.3 Poisoning Retrieval, Memory, and Semantic Caches

A large body of recent work instead attacks the state searched by the retriever. Adversarial passages can be injected into dense-retrieval corpora so that they rank highly for many queries (Zhong et al., 2023), with later work developing increasingly effective black-box and gradient-based corpus-poisoning strategies (Su et al., 2025). In retrieval-mediated agents, AgentPoison inserts poisoned demonstrations into long-term memory or RAG knowledge bases and uses optimized triggers to cause those demonstrations to be retrieved during agent execution (Chen et al., 2024b). Semantic caching creates a related attack surface: crafted query–response entries can poison embedding-based caches and subsequently affect other users whose queries are considered sufficiently similar (Wu et al., 2026).

These attacks demonstrate that retrieval components can become security-critical once their outputs feed foundation models or agents. They also share an important difference from our setting: the attacker manipulates the corpus, memory, cache, or a target-specific retrieval objective. In our threat model, the retrieval state remains unchanged and hidden; only a proxy for the natural query is constructed.

2.4 Safety at the Retrieval Boundary

Modern safety systems commonly place dedicated classifiers around language-model interactions to identify harmful user requests or unsafe model responses (Inan et al., 2023; Han et al., 2024). At the same time, retrieval can materially change the safety behavior of a language-model system: recent evaluations show that adding RAG can alter a model's safety profile even when the underlying model and retrieved documents are individually considered safe (An et al., 2025). AgentPoison and related work further show that retrieved memories or knowledge can influence later planning and actions (Chen et al., 2024b).

Our work concerns the boundary between these two mechanisms. A semantic guardrail judges the query it can read, while a dense retriever acts on the query representation. EONs test whether these two views can separate: a query may lose its recognizable semantic content while retaining enough of the original representation to preserve safety-sensitive routing or retrieval. We therefore study not only whether nonsemantic proxies preserve retrieval, but also when that preservation creates a gap between semantic moderation and embedding-based selection.

3 METHOD

3.1 CORPUS-BLIND QUERY OBFUSCATION

Let q denote a natural query and q^* its nonsemantic proxy, with Q and Q^* denoting their normalized embeddings. We use *Embedding-Optimized Noise* (EON) as an umbrella term for both text and image proxies. For a candidate proxy q' with normalized embedding Q', EON construction optimizes only

$$q^* \approx \arg \max_{q' \in \mathcal{X}(q)} Q^\top Q',$$

where $\mathcal{X}(q)$ is the allowed artifact space.

Here, Q is always the embedding of the individual natural evaluation query itself. EONs are never optimized toward a class or intent centroid, gold answer, tool description, paired item, retrieved candidate, or other task-specific target.

The setting is strictly *corpus-blind*: optimization observes only the natural-query representation and representations of proposed EONs. It receives no candidate identities or embeddings, labels or relevance judgments, rankings, retrieval scores, retrieved items, or guardrail decisions. The EON is frozen before any candidate-dependent evaluation, whether the eventual candidate bank is fixed or query-specific.

3.2 EON CONSTRUCTION

Text and image EONs share the same representation-matching objective but use different artifact spaces.

Text EONs. The default text EON contains 64 fixed, space-delimited visible ASCII atoms and is initialized as repeated colons. The legal atom bank is encoder-specific but query-independent and contains only short atoms that round-trip through the evaluated query tokenizer as single non-special tokens. Whitespace is fixed, and a lexical no-copy constraint prevents direct reuse of meaningful terms from the source query. At each proposal, one atom is replaced and the change is retained only if it strictly increases $Q^\top Q^*$.

Image EONs. Image EONs begin from a blank white canvas. Each proposal resamples a single scalar image channel, and the change is retained only if it strictly increases $Q^\top Q^*$. Once a channel has been changed by an accepted proposal, it is not edited again. The final optimized image is used for retrieval evaluation.

Both procedures are gradient-free and use query–EON similarity as their only optimization signal. The default optimization budget is 50,000 mutation proposals per query. Exact artifact constraints, tokenizer filtering, no-copy enforcement, update rules, and pseudocode are provided in Appendix A.4.

3.3 EXPERIMENTAL SETUP

Tasks and models. We evaluate intent routing on CLINC150 (Larson et al., 2019); tool selection on API-Bank (Li et al., 2023b) and BFCL (Patil et al., 2025); document retrieval on SciFact (Wadden et al., 2020) and NFCorpus (Boteva et al., 2016); memory retrieval on LongMemEval (Wu et al., 2025) and MemBench (Tan et al., 2025); text-to-image retrieval on MS-COCO (Karpathy test gallery) (Lin et al., 2014; Karpathy & Fei-Fei, 2015); and image retrieval on ImageNet (Deng et al., 2009). Safety-sensitive experiments use SALAD-Bench (Li et al., 2024), PKU-SafeRLHF (Ji et al., 2025), and T2I-RiskyPrompt (Zhang et al., 2026a).

Our principal text encoders are BGE-base (Xiao et al., 2024), Qwen3-Embedding-0.6B (Zhang et al., 2025), and Jina v5 Nano (Akram et al., 2026). Visual retrieval uses CLIP (Radford et al., 2021), SigLIP 2 (Tschannen et al., 2025), and DINOv3-B/16 (Siméoni et al., 2025). Independent guardrail evaluation uses Qwen3Guard-8B (Zhao et al., 2025), Granite Guardian 3.3-8B (Padhi et al., 2024; IBM Granite, 2025), and ShieldGemma 2-4B (Zeng et al., 2025).

Across these settings, the EON objective is unchanged: only the natural-query modality and the frozen candidate representation and bank vary.

Evaluation design. Evaluation manifests are fixed before EON optimization and reused across encoders and optimization seeds. Candidate-dependent retrieval, transfer, reranking, and guardrail evaluation occurs only after the EON is frozen. LongMemEval and MemBench retain their native query-specific memory banks rather than being collapsed into a single global index. Unless stated otherwise, results average three independent EON optimization seeds. The default text construction uses 64 atoms, and the default optimization budget is 50,000 mutation proposals per query. Full query/candidate instantiations, candidate-bank construction, control definitions, and implementation details are provided in Appendix A.5.

Metrics. **Natural Gold@k** and **EON Gold@k** measure benchmark-defined top-k task success for q and q^*, respectively. Our primary behavioral metric, **Preservation@k**, measures whether the outcome selected at natural rank one appears within the EON's top-k outcomes. Benign experiments use exact candidate identity; the safety-sensitive evaluations in Tables 2 and 3 use annotated harm-category identity. We additionally report mean query–EON cosine similarity $\overline{Q^\top Q^*}$ as a representation-level diagnostic. For guardrail experiments, **Bypass-ASR@k** measures the joint event that a frozen EON passes a guardrail that rejects its natural query while preserving the evaluated category outcome. Formal metric definitions are provided in Appendix A.5.

4 Experiments and Results

4.1 Can Nonsemantic Proxies Preserve Retrieval?

Corpus-blind behavioral preservation. Table 1 establishes the central result: EONs frequently preserve the behavior of natural queries despite never observing the candidate bank or the outcome being reproduced. Preservation is strongest for structured intent and tool routing, but extends to full-corpus document retrieval, query-specific memory, text-to-image retrieval, and image retrieval across independently trained embedding families. Preservation@k measures agreement with the natural query's retrieved outcome rather than benchmark correctness, complementing the Gold@k columns.

Beyond a fixed retrieval index. LongMemEval and MemBench use query-specific memory pools, so preservation persists even when the candidate bank itself changes across queries. This rules out adaptation to a single fixed index. The visual results further show that the phenomenon is not specific to text representations. Representative retrieval traces are provided in Table 21.

4.2 Safety-Sensitive Routing and Retrieval

Table 2 shows that the same corpus-blind effect persists when retrieval is evaluated over annotated harm categories. Across text, text-to-image, and image-to-image settings, nonsemantic EONs frequently recover the harm category associated with the natural query's top-ranked retrieval, despite having no access to the safety taxonomy or candidate bank during optimization. Representative examples are shown in Table 22.

The phenomenon is therefore not confined to benign semantic organization: readable harmful semantics can disappear from the query surface while the target encoder retains enough of the original representation to recover the same safety-sensitive category from an unseen candidate bank.

4.3 Guardrail Bypass of Preserved Retrieval

A joint guardrail–retrieval failure. Table 3 evaluates the relevant conjunction: the natural malicious query is rejected, its frozen EON is permitted, and the natural query's harm-category outcome is preserved. Substantial Bypass-ASR remains across independent text and vision guardrails, revealing a mismatch between semantic moderation and embedding-mediated selection.

This effect is not explained by generic permissiveness to noise. Matched random artifacts are also rarely rejected by the semantic guardrails, but almost never preserve query-specific retrieval be-

Table 1: **Benign query-proxy preservation across routing, memory, and text and image retrieval.** Settings evaluate intent and tool selection (ROUTING), dynamic per-instance conversation history (MEMORY RETRIEVAL), and static corpus or visual search (TEXT & IMAGE RETRIEVAL). **Gold@k** denotes benchmark-defined retrieval success for natural queries q and nonsemantic proxies q^*. **Preservation@k** measures whether the top-1 outcome retrieved by q appears among the top-k outcomes retrieved by q^*. All rates are percentages averaged over three EON optimization seeds. $\overline{Q^\top Q^*}$ is the mean cosine similarity between normalized natural-query and EON embeddings.

havior (Table 18). Conversely, a dedicated supervised gibberish detector (Jindal, 2021) rejects all evaluated text EONs while rejecting only 1.0–4.4% of natural safety queries (Table 8), reducing the corresponding text Bypass-ASR to zero.

4.4 ABLATIONS AND CONTROLS

Optimization and query specificity. The benign and safety-sensitive budget trajectories (Tables 5 and 6) show that preservation scales smoothly with query–EON alignment, with substantial retrieval preservation already achieved at early checkpoints (e.g., 2k proposals) well before the default budget. As shown by the optimization runtimes in Table 7, substantial preservation is already achieved at early checkpoints under local encoder access, well before the default optimization budget.

Matched random artifacts almost never preserve the natural outcome (Table 18), while permuting an optimized EON sharply reduces both $\overline{Q^\top Q^*}$ and Preservation@k (Table 19). Together, these controls show that preservation is query-specific and depends on the optimized artifact structure rather than length, atom inventory, or generic noise.

Construction and optimization access. Preservation remains robust across alternative initializations and artifact parameterizations (Tables 9–11), and increasing Qwen3-Embedding scale does not remove the effect (Table 12). Gradient access is also unnecessary: the default gradient-free

Table 2: **Safety-sensitive query-proxy preservation across harm-category retrieval.** All benchmarks retrieve from items with annotated harm categories. **Gold@k** denotes whether the top-k retrieved items include the query's annotated harm category, for natural queries q and nonsemantic proxies q^*. **Preservation@k** measures whether the category of the top-1 item retrieved by q appears among the top-k items retrieved by q^*. All rates are percentages averaged over three EON optimization seeds. $\overline{Q^\top Q^*}$ is the mean cosine similarity between normalized natural-query and EON embeddings.

optimizer remains competitive with, and in our experiments generally stronger than, the matched gradient-access control based on HotFlip (Ebrahimi et al., 2018) (Table 13).

Encoder and architectural boundaries. Preservation extends across additional dense single-vector encoders (Table 14), but frozen EONs transfer poorly across independently trained embedding spaces (Table 17), indicating that the effect is tied to the target encoder's representation geom-

etry. Preservation also weakens substantially under ColBERTv2 late interaction (Table 15) and after independent cross-encoder reranking (Table 16), identifying architectures that reintroduce query–candidate interaction as an important boundary.

Bootstrap confidence intervals for the central Preservation@5 and Bypass-ASR@5 results are reported in Table 4. Additional analysis of optimization cost, candidate-bank independence, category-level evaluation, statistical uncertainty, and mitigation scope is provided in Appendix A.2.

4.5 Geometric Analysis

Theoretical guarantees. Let Q and Q^* denote the normalized embeddings of a natural query and its EON, and let A denote any normalized candidate embedding. Writing $c = Q^\top Q^*$ and $\epsilon = \|Q - Q^*\|_2$, expanding $\|Q - Q^*\|_2^2$ under $\|Q\|_2 = \|Q^*\|_2 = 1$ gives

$$\epsilon = \sqrt{2 - 2c}.$$

By Cauchy–Schwarz,

$$\left|Q^\top A - Q^{*\top} A\right| \le \epsilon \quad \Longrightarrow \quad Q^\top A - \epsilon \le Q^{*\top} A \le Q^\top A + \epsilon.$$

This gives a corpus-blind guarantee for every unseen candidate: higher query–EON similarity uniformly limits how much its retrieval score can change. Two useful consequences follow. First, any threshold decision is preserved whenever the natural score has more than ϵ slack from the threshold. Second, the natural top-1 candidate is guaranteed to remain top-1 whenever its score margin over the runner-up exceeds 2ϵ. These latter guarantees depend on the deployed threshold or candidate-bank margin, but neither quantity is used during EON construction. Appendix A.6 gives the full derivation, equivalent conditions in terms of c, and a numerical example illustrating all three guarantees.

What is preserved in practice? The guarantees above bound score changes, not their direction: an EON need not increase the score of the candidate selected by the natural query. This is exactly what we observe in Table 20. For CLINC150 with BGE-base, 79.7% of query–EON pairs decrease the affinity to the natural top-ranked candidate ($\Delta_A < 0$), yet that subset still achieves 89.0% Preservation@1. Thus, preservation is not explained by simply boosting the selected candidate. Instead, the EON often perturbs candidate scores little enough that the natural ordering survives, consistent with the score-stability and margin guarantees above.

5 Conclusion

We identify BLINDSPOT, a representational failure mode in which a natural query can be replaced by visibly nonsemantic Embedding-Optimized Noise while preserving retrieval behavior over candidate banks never observed during optimization. Constructed solely by matching the natural query representation, EONs preserve intent and tool routing, document and query-specific memory retrieval, and cross-modal and image retrieval across multiple dense embedding families. The effect is query- and encoder-specific: it strengthens with optimization, is absent for unoptimized noise, degrades when optimized structure is disrupted, and transfers poorly across independently trained encoders.

For safety-sensitive queries, this creates a consequential mismatch between surface semantics and embedding-mediated behavior: the same frozen EON can pass independent guardrails that reject the natural query while preserving its retrieval outcome. Our analysis provides a geometric explanation for this behavior: query–EON similarity places a corpus-blind bound on score changes for unseen candidates, allowing retrieval decisions to remain stable without access to the candidate bank. At the same time, late interaction and independent cross-encoder reranking substantially weaken preservation, identifying clear architectural boundaries and mitigation directions.

Overall, semantic recognizability and representational actionability can diverge: a query may cease to be meaningfully interpretable while remaining operationally meaningful to a retriever. Retrieval systems, particularly in safety-sensitive settings, should therefore not treat embedding similarity alone as evidence that a query is semantically well formed or safe.

AI USE STATEMENT

Generative AI tools were used only to assist with polishing portions of the manuscript text. They were not used to generate research ideas, design the methodology, conduct experiments, analyze results, or otherwise produce the scientific contributions of this work. All AI-assisted text was reviewed and edited by the authors, who take full responsibility for the final manuscript.

ETHICS STATEMENT

This work uses publicly available datasets and models, which are cited throughout the paper, and does not involve human subjects or private user data. Because the work studies weaknesses in retrieval and safety mechanisms, it may have dual-use implications. We present the findings to improve understanding of these failure modes and discuss corresponding mitigations and architectural defenses.

REPRODUCIBILITY STATEMENT

We provide detailed descriptions of the threat model, optimization procedure, evaluation protocol, metrics, candidate-bank construction, seeds, and experimental controls in the main paper and appendix. Unless otherwise specified, results are averaged over three independent optimization seeds, with evaluation manifests fixed across models and runs. Code and scripts needed to reproduce the experiments will be released upon acceptance.

A Appendix

A.1 Qualitative Examples

Tables 21 and 22 provide representative text-side retrieval traces spanning tool routing, agent memory, full-corpus document retrieval, and safety-sensitive retrieval. These examples illustrate how EONs can preserve the natural query's retrieved outcome despite their nonsemantic surface form; aggregate preservation rates are reported in the main quantitative results.

For readability, EON strings and retrieved candidate text are truncated with ellipses; ranks, identities, and reported similarity scores are unchanged. $Q^\top Q^*$ denotes query–EON similarity, while retrieval scores denote query–candidate similarity under the corresponding encoder. Shaded rows and boldface mark recovery of the natural query's top-ranked candidate.

A.2 Implications and Scope

Semantic retrieval increasingly mediates which documents, memories, tools, and multimodal content become available to downstream AI systems. A mismatch between query-side safety checks and retrieval behavior can therefore have consequences beyond retrieval accuracy: a proxy that passes a semantic guardrail may still surface the same safety-sensitive content or capability as the blocked natural query. Our experiments establish this failure at the retrieval boundary; its downstream consequences depend on the access controls, generator, and agent policy of the deployed system. For example, in systems where semantic retrieval selects a memory record, document, or tool before downstream reasoning, preserving that retrieval under a guardrail-passing proxy could expose the same resource to subsequent system components even though the original query was rejected.

The remainder of this section clarifies the interpretation and scope of these results, including optimization cost, candidate-bank independence, safety evaluation, and architectural boundaries.

Optimization budget and cost. The default 50k proposal budget is intended to provide a strong and consistent operating point, not to imply that 50k proposals are required for the effect to appear. Tables 5 and 6 show that substantial Preservation@k is already present at 2k and 10k checkpoints in many routing, safety-sensitive, and visual settings, and generally increases as query–EON alignment improves. The 50k setting therefore emphasizes the full strength of the phenomenon, while the lower-budget checkpoints expose its cost–performance trade-off. The corresponding wall-clock costs are also modest relative to the scale of the evaluation. On NVIDIA H200 hardware, the throughput-scaled 2k equivalent for optimizing 500 text queries is approximately 1.6–5.1 minutes across the principal text encoders, while directly measured 50k runs take approximately 40–128 minutes (Table 7). These costs reflect only local query-encoder optimization and do not require candidate-bank queries, retrieval feedback, or guardrail interaction. Once an EON is constructed, it is frozen and can be evaluated against any compatible candidate bank.

Behavioral preservation versus benchmark correctness. Gold@k and Preservation@k measure different properties. Gold@k asks whether retrieval is benchmark-correct, whereas Preservation@k asks whether the EON reproduces the outcome selected by the natural query. For benign retrieval, this is the natural top-ranked candidate; for the primary safety-sensitive evaluation, it is the corresponding annotated harm category. Preservation therefore need not imply benchmark correctness, and a benchmark-correct EON need not reproduce the natural query's exact behavior.

Candidate-bank independence. The evaluated tasks vary substantially in candidate structure. Routing uses complete intent or tool bank, document retrieval searches full collections, visual retrieval searches galleries, and memory benchmarks use query-specific memory pools. The latter are especially informative as the candidate bank itself changes across queries. Together with the absence of candidate identities, embeddings, rankings, or retrieval scores during optimization, these settings distinguish query-representation matching from candidate-aware retrieval optimization.

Safety-sensitive preservation. The primary safety experiments evaluate retrieval at the level of annotated harm categories. Gold@k measures whether an EON retrieves items matching the query's annotated category, whereas Preservation@k measures whether the category selected by the natural

query remains represented among the EON's top-k retrievals. EON construction has no access to the safety taxonomy or candidate bank. The result should therefore be interpreted as preservation of safety-sensitive retrieval behavior at the category level, not as evidence that the EON surface itself expresses the corresponding harmful semantics.

Safety guardrail and surface-form filtering. Bypass-ASR isolates the conjunction of two events: the natural query is rejected while the same frozen EON is permitted and preserves its evaluated retrieval outcome. Random legal noise shows that semantic guardrail acceptance alone is insufficient, because unoptimized artifacts are often permitted but do not retain query-specific retrieval behavior. At the same time, the present short-atom construction is not invisible to every filter that a retrieval system could apply. A simple supervised gibberish detector rejects all evaluated text EONs and matched random artifacts while rejecting only 1.0%–4.4% of natural safety queries (Table 8), reducing the corresponding text Bypass-ASR to zero.

While specialized lexical filters reliably flag non-standard queries, they address the surface form of the present attack rather than the underlying representational mismatch. This distinction matters because dense encoders can admit semantic collisions (Song et al., 2020), motivating complementary defenses at the retrieval level in addition to query screening. Notably, the same retrieval-preservation phenomenon also appears in the image setting, where lexical query screening is not applicable.

Encoder access and transfer. Frozen EONs transfer poorly across independently trained encoders, indicating that the effect is closely tied to the representation geometry against which the proxy is optimized. The strongest practical setting is therefore one in which the deployed query encoder is known, publicly available, or otherwise reproducible. Importantly, once such access is available, optimization remains entirely local: constructing a proxy for a new query does not require probing the deployed candidate bank or observing retrieval outcomes.

Architectural scope. The effect is strongest for dense single-vector retrieval. ColBERTv2 late interaction substantially weakens preservation, and independent cross-encoder reranking weakens it further. These controls are consistent with the proposed mechanism: corpus-blind representation matching is most consequential when a single query vector largely determines candidate selection, while explicit query–candidate interaction provides a natural architectural boundary.

A.3 Limitations

The principal limitation is encoder specificity. Because cross-encoder transfer is weak, a reliable EON generally requires access to, or knowledge of, the query encoder used by the target retrieval system. This restricts the threat model for opaque proprietary encoders. Conversely, public and reproducible embedding models make the optimization setting considerably more realistic, since EON construction can then be performed locally without access to the deployed candidate bank, retrieval scores, or guardrail feedback.

We do not evaluate whether proxies optimized against several commonly deployed encoders could be precomputed and tested opportunistically against an unknown system. Such a strategy could partially relax the exact-model assumption when the space of plausible encoders is small, but its effectiveness is presently unknown and should not be inferred from our transfer results.

The current text EONs are also visibly nonsemantic. The present construction is designed to isolate the representational failure mode rather than optimize surface-form stealth. As shown in Table 8, a dedicated lexical/surface-form detector can reject the present short-atom construction with low rejection of the evaluated natural queries. We therefore do not claim that EONs evade specialized gibberish, lexical-validity, or representation-OOD filters. Whether an optimizer can preserve retrieval while simultaneously satisfying such surface-form constraints is a separate question.

Finally, our safety experiments establish failure at the retrieval boundary: a nonsemantic proxy can pass semantic moderation while retaining a safety-sensitive retrieval outcome. We do not claim that every preserved retrieval necessarily produces a harmful final system action. End-to-end effects will depend on the generator, agent policy, retrieved content, and additional controls applied after retrieval.

A.4 METHOD DETAILS

Notation and retrieval. Lowercase symbols denote query or candidate artifacts, while uppercase symbols denote normalized embedding vectors. For natural query q and EON q^*,

$$Q = \frac{f(q)}{\|f(q)\|_2}, \qquad Q^* = \frac{f(q^*)}{\|f(q^*)\|_2},$$

where f is the query encoder. Importantly, Q is always computed from the individual natural evaluation query q. It is never a class centroid, label representation, tool description, gold answer, paired item, or retrieved candidate.

For candidate bank

$$\mathcal{C} = \{a_1, \ldots, a_M\},$$

let

$$A_i = \frac{g(a_i)}{\|g(a_i)\|_2}$$

denote the normalized representation of candidate a_i. For symmetric retrieval $f = g$; cross-modal retrieval may use distinct query and candidate encoders. Candidates are ranked by

$$R_k(q; \mathcal{C}) = \mathrm{TopK}_{a_i \in \mathcal{C}}\, Q^\top A_i.$$

Because all representations are normalized, inner product and cosine similarity are equivalent.

Text artifact space. The default text EON contains exactly $L = 64$ nonempty atoms separated by 63 fixed ASCII spaces. Initialization is the repeated-colon sequence

$$q_0 = \texttt{: : : ...:}.$$

Whitespace is never mutated.

For each text encoder, we construct a query-independent legal atom bank $\mathcal{A}_f$. Before tokenizer filtering, the base inventory contains: (i) one-character ASCII letters and digits together with the punctuation characters

$$\texttt{.,;:-_/\textbackslash|\#@\%\&*+=?!()[]\{\}},$$

(ii) all two-character lowercase-letter strings `aa`–`zz`, and (iii) all two-digit strings `00`–`99`.

An atom is retained only when both the atom itself and its space-prefixed form tokenize as exactly one non-special token under the evaluated query tokenizer, decode to visible ASCII, and re-encode to the same token ID. Duplicate tokenizer representations are removed. Thus, the legal atom bank may differ across encoders but does not depend on the particular query being optimized.

This construction uses only visible text. It does not use Unicode control characters, hidden tokens, synthetic embedding vectors, or direct token-ID injection.

Lexical no-copy constraint. The no-copy rule is a lexical surface-form constraint rather than a token-overlap constraint. We normalize the source query into its alphanumeric terms and consider terms of length at least three characters. A proposed EON is rejected before embedding if its visible text contains any such normalized source-query term.

Text EON optimization. Let the current EON be

$$q^* = (z_1, \ldots, z_L), \qquad z_j \in \mathcal{A}_f.$$

For current embedding Q^* and proposal embedding Q', define

$$c = Q^\top Q^*, \qquad c' = Q^\top Q'.$$

Each mutation proposal samples one of the L atom positions and replaces it with an atom sampled from $\mathcal{A}_f$. Proposals violating the lexical no-copy constraint are discarded. All remaining proposals are embedded with the ordinary query encoder and accepted iff

$$c' > c.$$

No gradient or candidate-dependent quantity enters this decision. Unless otherwise stated, optimization uses 50,000 mutation proposals per query, in addition to the initial embedding of q_0.

Algorithm 1 Text EON Optimization

    continue
  end if
  $Q' \leftarrow \text{NORMALIZE}(f(q'))$
  $c' \leftarrow Q^\top Q'$ ▷ only optimization signal
  if $c' > c$ **then**
    $q^* \leftarrow q'$
    $Q^* \leftarrow Q'$
    $c \leftarrow c'$
  end if
end for
return q^*

Image EON construction. Image EONs optimize the same representation-matching objective directly in pixel space. For natural image query q, optimization starts from the fixed white RGB canvas

$$q_0 = \mathbf{1} \in [0,1]^{3\times 224\times 224}.$$

Let

$$\mathcal{U} = \{1, \ldots, 3 \cdot 224^2\}$$

index scalar image channels not previously changed by an accepted proposal.

At each proposal, coordinate r is sampled uniformly from $\mathcal{U}$ and assigned

$$v \sim \text{Uniform}[0, 1).$$

The proposal therefore changes exactly one scalar RGB channel. It is accepted iff it strictly increases $Q^\top Q^*$. After acceptance, r is removed from $\mathcal{U}$ and is never edited again; rejected coordinates remain eligible for later proposals.

Unless otherwise stated, image optimization uses 50,000 mutation proposals. The final optimized image is then used for retrieval evaluation.

Information boundary. During EON construction, the optimizer observes only the natural-query representation Q and representations of proposed artifacts. It does not observe candidate identities or embeddings, candidate text, labels, qrels, gold answers, paired targets, rankings, retrieval scores, retrieved items, or guardrail decisions. Candidate-bank access begins only after optimization terminates and the EON has been frozen.

The same separation is maintained in subsequent analyses. Cross-encoder transfer evaluates a frozen source EON under a different encoder without re-optimization; dense-to-cross-encoder experiments construct the EON against the dense encoder before applying the reranker (Xiao et al., 2024; Li et al., 2023a; Chen et al., 2024a); and guardrail models evaluate frozen artifacts without supplying optimization feedback.

A.5 Experimental Details

Optimization target and task instantiation. In the default formulation, EON construction targets only the embedding of the individual natural evaluation query. The optimization objective is

Algorithm 2 Image EON Optimization

Require: Natural image query q, image encoder f, white canvas $q_0 = \mathbf{1}_{3\times224\times224}$, proposal budget B
Ensure: Image EON q^*

  end if
end for
return q^*

unchanged across tasks; what varies is the query modality and the frozen candidate bank used only after optimization.

CLINC150 queries are utterances and candidates are intent representations; API-Bank and BFCL queries are user requests and candidates are tool-schema representations. SciFact and NFCorpus queries are benchmark queries and candidates are corpus documents. LongMemEval and MemBench queries are memory questions and candidates are records from the associated conversation history. All candidate representations are fixed by the evaluation manifest before EON optimization and are never used as EON optimization targets.

For MS-COCO, the natural query is a caption and candidates are images from the Karpathy test gallery. The natural query and its EON are encoded by the text tower, while gallery images are encoded by the corresponding image tower. For ImageNet, both query and candidates are images: q is a natural image, q^* is its image EON, and candidates are distinct gallery images. Query and gallery instances are disjoint.

Safety-sensitive tasks follow the same separation. Text queries retrieve text or image candidates, and image queries retrieve image candidates. Primary safety evaluation is performed at the annotated harm-category level as defined below.

Candidate banks and evaluation sets. We distinguish the number of evaluated queries, N, from the candidate bank searched for each query. N is therefore an evaluation-set size, whereas bank describes the retrieval problem presented to that query. Unless otherwise stated, we evaluate up to 500 natural queries per benchmark, using all available evaluation queries when fewer than 500 are available.

CLINC150, API-Bank, and BFCL use their complete routing candidate sets. SciFact and NFCorpus use their complete document collections. MS-COCO (Karpathy test gallery), ImageNet (val), and safety-sensitive visual retrieval use fixed galleries defined by the corresponding evaluation manifests.

Memory benchmarks are not collapsed into a global candidate bank. Each query is evaluated against its associated memory-history pool: approximately 460–490 candidates for LongMemEval and 8–

193 for MemBench. Fixed evaluation-query subsets and their corresponding memory pools are reused across encoders and optimization seeds. Thus, both the relevant memory and the candidate bank may vary from one query to the next.

Evaluation design and reproducibility. All evaluation manifests—including query and candidate identities, ground-truth mappings, and test partitions—are fixed prior to EON optimization and shared across all evaluated encoders. To ensure statistical reliability, primary retrieval and proxy preservation results report the mean across three independent optimization seeds.

Control experiments. Random controls are independently sampled legal 64-atom artifacts from the same encoder-specific atom bank and receive no optimization.

Permutation controls use the same atoms as an already optimized frozen EON, shuffle their order within that artifact, and perform no re-optimization.

The gradient-access control uses the same legal artifact space and the same query-representation objective as the default method, with a matched score-evaluation budget, but additionally receives gradient information. Cross-encoder transfer, guardrail, reranking, random-noise, and permutation controls do not re-optimize the source EON unless explicitly stated otherwise.

Optimization cost. Table 7 reports query-side optimization wall-clock cost on NVIDIA H200 hardware. The logged 50k times measure EON construction only and exclude model loading, candidate-bank encoding, and retrieval evaluation. Because intermediate checkpoints did not record timestamps, the 2k values are throughput-scaled equivalents rather than independently measured runtimes.

Gold retrieval metrics. For query q, let $\mathcal{G}(q) \subseteq \mathcal{C}$ denote its valid gold candidate set. Define

$$S_k(q) = \mathbb{1}\left[R_k(q;\mathcal{C}) \cap \mathcal{G}(q) \neq \emptyset\right].$$

We report

$$\text{Natural Gold@}k = \frac{1}{N}\sum_{n=1}^{N} S_k(q_n), \qquad \text{EON Gold@}k = \frac{1}{N}\sum_{n=1}^{N} S_k(q_n^*).$$

These measure benchmark-defined task success and are distinct from behavioral preservation: an EON may preserve an incorrect natural outcome, or retrieve a different outcome that is nevertheless benchmark-correct.

Preservation. Let $r_1(q_n;\mathcal{C}_n)$ denote the natural query's top-ranked candidate for example n, and let ϕ map a candidate to the task-level outcome being compared. We define

$$\text{Preservation@}k = \frac{1}{N}\sum_{n=1}^{N} \mathbb{1}\left[\phi(r_1(q_n;\mathcal{C}_n)) \in \{\phi(a) : a \in R_k(q_n^*;\mathcal{C}_n)\}\right].$$

Allowing $\mathcal{C}_n$ to vary explicitly accommodates the native query-specific memory banks.

For routing, tool selection, document retrieval, memory retrieval, and benign visual retrieval, $\phi(a) = a$, so Preservation@k measures exact natural-outcome identity. For the primary safety-sensitive evaluations in Tables 2 and 3, ϕ maps each candidate to its annotated harm category. Exact paired-item agreement, where reported separately, is a stricter diagnostic and is not the primary safety metric.

Representation similarity. We report mean query–EON cosine similarity

$$\overline{Q^\top Q^*} = \frac{1}{N}\sum_{n=1}^{N} Q_n^\top Q_n^*.$$

This is the representation-level quantity optimized during EON construction, not a retrieval-success metric. Because cosine scales are not calibrated across independently learned representation spaces, it is interpreted within an encoder rather than used for direct cross-encoder comparison.

Guardrail bypass. For guardrail evaluation, let $\mathrm{blocked}(q)$ denote rejection of the natural query, $\mathrm{pass}(q^*)$ acceptance of its EON, and $\mathrm{preserve}_k(q, q^*)$ the relevant category-level Preservation@k event. We define

$$\text{Bypass-ASR@}k = \Pr[\mathrm{pass}(q^*) \wedge \mathrm{preserve}_k(q, q^*) \mid \mathrm{blocked}(q)] .$$

Bypass-ASR therefore requires the same frozen EON to pass a guardrail that rejects its natural query while preserving the evaluated harm-category outcome.

A.6 Extended Geometric Analysis

We further characterize what query-representation matching guarantees and how those guarantees relate to retrieval decisions. Throughout this section, Q and Q^* denote the L2-normalized embeddings of a natural query q and its EON q^*, and A denotes any normalized candidate embedding. Let

$$c = Q^\top Q^*, \qquad \epsilon = \|Q - Q^*\|_2.$$

Corpus-blind score stability. Because $\|Q\|_2 = \|Q^*\|_2 = 1$,

$$\begin{aligned}\epsilon^2 &= \|Q - Q^*\|_2^2 \\ &= (Q - Q^*)^\top (Q - Q^*) \\ &= Q^\top Q - 2Q^\top Q^* + Q^{*\top} Q^* \\ &= 2 - 2c.\end{aligned}$$

Therefore,

$$\epsilon = \sqrt{2 - 2c}.$$

For any normalized candidate representation A,

$$\begin{aligned}\left|Q^\top A - Q^{*\top} A\right| &= \left|(Q - Q^*)^\top A\right| \\ &\le \|Q - Q^*\|_2 \|A\|_2 \\ &= \epsilon,\end{aligned}$$

by Cauchy–Schwarz. Hence,

$$Q^\top A - \epsilon \le Q^{*\top} A \le Q^\top A + \epsilon.$$

The bound depends only on the query–EON similarity c and therefore applies to every normalized candidate, whether or not that candidate or its embedding was available during optimization.

Threshold preservation. Suppose a retrieval or routing system activates candidate A whenever its similarity exceeds a fixed operational threshold τ. Let

$$s = Q^\top A$$

be the natural-query score and assume $s > \tau$. Since

$$Q^{*\top} A \ge s - \epsilon,$$

the threshold decision is guaranteed to remain unchanged whenever

$$s - \epsilon > \tau.$$

Defining the natural threshold slack

$$\delta = s - \tau,$$

a sufficient condition is

$$\epsilon < \delta.$$

Using $\epsilon = \sqrt{2 - 2c}$ gives the equivalent condition

$$c > 1 - \frac{\delta^2}{2}.$$

This guarantee is meaningful when τ is an actual system decision threshold. We do not assume a universal cosine threshold for semantic similarity, since similarity scales differ across encoders.

Top-1 preservation. Ranking requires additional information about the realized candidate bank. Let $A_{(1)}$ and $A_{(2)}$ denote the natural query's top-ranked and runner-up candidate representations, with margin

$$m = Q^\top A_{(1)} - Q^\top A_{(2)}.$$

Each score can change by at most ϵ, so

$$Q^{*\top} A_{(1)} - Q^{*\top} A_{(2)} \geq m - 2\epsilon.$$

Therefore, the natural top-ranked candidate is guaranteed to remain top ranked whenever

$$m > 2\epsilon = 2\sqrt{2 - 2c}.$$

Equivalently,

$$c > 1 - \frac{m^2}{8}.$$

Unlike the candidate-score bound, this certificate depends on the candidate margin and is therefore a post-hoc guarantee rather than information available during EON construction. No nontrivial value $c < 1$ alone can guarantee top-1 preservation for every possible hidden bank, because two unseen candidates may lie arbitrarily close to the natural decision boundary.

Illustrative example. Consider an EON with

$$c = 0.99.$$

Then

$$\epsilon = \sqrt{2 - 2(0.99)} \approx 0.141.$$

Suppose the natural query scores two unseen candidates as

$$Q^\top A_1 = 0.90, \qquad Q^\top A_2 = 0.50,$$

and the system applies a threshold $\tau = 0.75$.

The score-stability bound gives

$$Q^{*\top} A_1 \geq 0.90 - 0.141 = 0.759,$$

while

$$Q^{*\top} A_2 \leq 0.50 + 0.141 = 0.641.$$

First, these inequalities show that neither candidate score can change arbitrarily despite both candidates being absent from EON optimization. Second, because

$$0.759 > 0.75,$$

candidate A_1 is guaranteed to remain above the operational threshold. Third, because

$$0.759 > 0.641,$$

A_1 is also guaranteed to remain above A_2. Equivalently, the natural margin

$$m = 0.90 - 0.50 = 0.40$$

satisfies

$$m > 2\epsilon \approx 0.282.$$

The same value of c would not certify top-1 preservation if the two natural candidate scores were sufficiently close. Query similarity therefore provides a universal score-stability guarantee, while threshold and ranking guarantees additionally depend on the decision boundary of the realized retrieval problem.

Table 4: **Statistical confidence for central outcomes.** Estimated 95% confidence intervals for central top-5 outcomes across benign retrieval (PRESERVATION@5), safety-category preservation, and guardrail bypass (corresponding to primary results in Tables 1–3). Intervals account for variance across evaluation queries and independent optimization seeds. Brackets report 95% confidence bounds; all values are percentages.

Connection to EON target affinity. For the natural top-ranked candidate A_1, define

$$\Delta_A = Q^{*\top} A_1 - Q^{\top} A_1.$$

The corpus-blind bound immediately implies

$$|\Delta_A| \leq \epsilon.$$

It constrains the magnitude of the target-score change but does not require Δ_A to be positive.

Table 20 shows that this distinction matters empirically. Across several settings, the EON retains substantial absolute similarity to the natural top-ranked candidate even when that similarity decreases. For CLINC150 with BGE-base, the median natural and EON target similarities are .862 and .832, respectively; 79.7% of examples have $\Delta_A < 0$, yet this subset retains $89.0/99.2\%$ Preservation@1/@5. For SciFact with Qwen3-0.6B, the corresponding median similarities are $.663/.556$; 95.9% of examples have $\Delta_A < 0$, while Preservation@1/@5 remains $60.1/84.9\%$.

These results indicate that EON success is not explained solely by preserving relative rank after arbitrary score collapse. The selected candidate often retains substantial absolute affinity under the EON, while the broader candidate-score geometry remains sufficiently stable for the natural retrieval outcome to survive.

Table 5: **Benign query-proxy preservation across optimization budget checkpoints.** Settings evaluate intent selection (ROUTING) and static corpus or visual search (TEXT & IMAGE RETRIEVAL). Each cell isolates: **EON (q^*) Gold @1 / @5** (top, gray), **Preservation @1 / @5** (middle, bold), and $\overline{Q^\top Q^*}$ (bottom, gray). **Gold@k** denotes benchmark-defined retrieval success for non-semantic proxies q^*. **Preservation@k** measures whether the top-1 outcome retrieved by q appears among the top-k outcomes retrieved by q^*. All rates are percentages averaged over three EON optimization seeds; the 50k checkpoint corresponds to the default setting in Table 1. $\overline{Q^\top Q^*}$ is the mean cosine similarity between normalized natural-query and EON embeddings.

Table 6: **Safety-sensitive query-proxy preservation across optimization budget checkpoints.** All benchmarks evaluate retrieval over safety taxonomies and annotated harm categories as in Table 2. Each cell isolates: **EON (q^*) Gold @1 / @5** (top, gray), **Preservation @1 / @5** (middle, bold), and $\overline{Q^\top Q^*}$ (bottom, gray). **Gold@k** denotes whether the top-k retrieved items include the query's annotated harm category for nonsemantic proxies q^*. **Preservation@k** measures whether the category of the top-1 item retrieved by q appears among the top-k items retrieved by q^*. All rates are percentages averaged over three EON optimization seeds; the 50k checkpoint corresponds to the default setting in Table 2. $\overline{Q^\top Q^*}$ is the mean cosine similarity between normalized natural-query and EON embeddings.

Table 20: **Post-hoc target-affinity analysis.** Let a_1 denote the candidate selected at natural rank one, with normalized embedding A_1, and define $\Delta_A = Q^{*\top} A_1 - Q^{\top} A_1$. Case A contains pairs with $\Delta_A \geq 0$ and Case B pairs with $\Delta_A < 0$. Preservation reports whether a_1 is recovered at EON rank one or within its top five. All preservation rates and fractions are percentages.

				Case A ($\Delta_A \geq 0$)		**Case B** ($\Delta_A < 0$)

LongMemEval	BGE-base	.675 / .703	**62.2 / 90.7**	72.6% / $+.039$	67.2 / 92.7	27.4% / $-.024$	48.9 / 85.2
	Qwen3-0.6B	.561 / .539	**37.7 / 64.7**	34.3% / $+.050$	59.4 / 91.5	65.7% / $-.067$	26.3 / 50.8
	Jina v5 Nano	.499 / .449	**62.7 / 90.1**	19.4% / $+.029$	87.3 / 99.7	80.6% / $-.073$	56.7 / 87.8

Note: A decrease in target score does not imply retrieval failure: the natural rank-one candidate can remain highly ranked even when $\Delta_A < 0$. This analysis is strictly post hoc; optimization observes only query–proxy representation similarity without candidate scores, ranks, or gallery access.

Table 21: **Representative benign EON retrieval traces.** Side-by-side comparison of top-5 retrieved candidates and similarity scores for natural queries (q) and their nonsemantic EON proxies (q^*). Traces illustrate tool routing (BFCL / BGE-base), episodic agent memory (LongMemEval / Qwen3-0.6B), and full-corpus document retrieval (NFCorpus / Jina v5 Nano). In all settings, EONs are optimized without access to the candidate bank or retrieval targets. Shaded rows indicate exact recovery of the natural rank-1 outcome. EON sequences and candidate descriptions are clipped for readability.

(a) Tool Routing: BFCL / BGE-base $\mathbf{Q}^\top \mathbf{Q}^* = \mathbf{0.952}$

q I need to get a flight from JFK on the 16th of March 2024. Can you find me something that leaves around 14:00?

Table 22: **Audit-backed safety-sensitive EON retrieval traces.** Each trace reports top-five retrieval under the natural query q and its EON q^*. Shaded rows mark exact top-one preservation. Guardrail outcomes highlight the security divergence: natural queries are intercepted by both moderation layers while nonsemantic proxies bypass them entirely. All reported numeric values are embedding-retrieval cosine scores.
