DISTRIBUTION-AWARE ROBUST BILEVEL OPTIMIZATION: QUANTILE-GUIDED HUBER UPDATES IN TWO-TIMESCALE STOCHASTIC APPROXIMATION

Anonymous authors
Paper under double-blind review

ABSTRACT

Heavy-tailed stochastic gradients can destabilize bilevel optimization by propagating lower-level errors into upper-level updates. We propose RQ-TTSA, a quantile-guided clipping framework for two-timescale stochastic approximation. The method uses a rolling buffer of gradient norms to adapt its clipping threshold, controlling the magnitudes of lower-level stochastic gradients while preserving their directions through radial rescaling. We further specify a predictable threshold variant that combines historical quantile estimates with bounded scale factors and an explicit polynomial growth schedule. This construction establishes pathwise threshold bounds and separates empirical scale adaptation from the growth conditions needed for convergence analysis. Experiments with the rolling-quantile implementation cover synthetic problems, vision benchmarks, stochastic games, and offline actor–critic learning. The reported results show lower mean final losses on the vision benchmarks and reduced actor-loss fluctuations in the offline reinforcement learning experiment, while stability gains vary across tasks. These findings suggest that recent gradient statistics can provide useful scale information for robust bilevel updates.

1 INTRODUCTION

Bilevel optimization (BLO) serves as the foundational framework for hierarchical decision-making, formulated as $\min_x F(x, y^*(x))$ subject to $y^*(x) \in \arg\min_y G(x, y)$. This nested structure underpins modern machine learning methods, including hyperparameter optimization Franceschi et al. (2018), meta-learning Hospedales et al. (2021), and actor–critic reinforcement learning Hong et al. (2022). In applications such as coreset selection and data reweighting Killamsetty et al. (2021), the upper-level objective relies critically on the stability of the lower-level solution. However, this dependency creates a fragile bottleneck: stochastic noise or instability in the lower-level optimization propagates to the hyper-gradient, frequently leading to the instability of the entire learning process.

To address the intractability of exact solvers, Two-Timescale Stochastic Approximation (TTSA) has become the standard for scalable BLO, achieving a sample complexity of $\mathcal{O}(\epsilon^{-3})$ under nonconvex–strongly convex assumptions Ji et al. (2021). Yet, these guarantees hinge on the assumption of light-tailed (bounded-variance) noise. In practice, this assumption is routinely violated in regimes characterized by sparse rewards in RL Zhang et al. (2019); Gorbunov et al. (2020) or data heterogeneity in federated learning Li et al. (2020). Under such heavy-tailed conditions, rare but extreme gradients destabilize the coupled dynamics, triggering numerical collapse that standard momentum or variance reduction techniques Cutkosky & Orabona (2019); Simsekli et al. (2019); Dagréou et al. (2022) fail to mitigate.

Prior literature has proposed two primary classes of stabilization techniques. Variance Reduction (VR) methods, such as SABA Dagréou et al. (2022) and blockwise VR Hu et al. (2023), integrate SVRG or SAGA estimators to diminish gradient noise. While theoretically powerful ($\mathcal{O}(\epsilon^{-2})$ rates), they incur significant memory overhead and typically assume bounded variance ($p = 2$), rendering them ineffective against heavy-tailed outliers. Adaptive Step-size and Momentum methods, such as BiSLS Fan et al. (2023) and accelerated robust optimization Gong et al. (2024), attempt to control

Table 1: Comparison of stochastic bilevel optimization solvers in the nonconvex-strongly-convex setting under smoothness assumptions on f and g. We omit variance reduction methods that assume mean-squared smoothness. The $\tilde{O}$ hides $\log(\epsilon^{-1})$. SC means strongly-convex. Heavy-tailed refers to p-th moment bounded for $p \in (1, 2]$ (infinite variance).

Method	Sample Complexity	(UL) f	(LL) g
TTSA Hong et al. (2022)	$\tilde{O}(\epsilon^{-3})$	$C_L^{1,1}$	SC and $C_L^{2,2}$
BiSLS Fan et al. (2023)	$\tilde{O}(\epsilon^{-3})$	$C_L^{1,1}$	SC and $C_L^{2,2}$
MA-SOBA Chen et al. (2024)	$O(\epsilon^{-2})$	$C_L^{1,1}$	SC and $C_L^{2,2}$
AccBO Gong et al. (2024)	$\tilde{O}(\epsilon^{-3})$	Unbounded Smooth	SC and $C_L^{2,2}$
RQ-TTSA (Ours)	$O(\epsilon^{-\frac{3p-2}{p-1}})$	$C_L^{1,1}$	SC and $C_L^{2,2}$
Method	**Noise Assumption**	**Hessian Inversion**	**Single-Loop**
TTSA Hong et al. (2022)	Bounded Variance	Neumann approx.	Yes
BiSLS Fan et al. (2023)	Bounded Variance	SGD	Yes
MA-SOBA Chen et al. (2024)	Bounded Variance	SGD	Yes
AccBO Gong et al. (2024)	Small Variance $O(\epsilon)$	SGD	Yes
RQ-TTSA (Ours)	Heavy-tailed ($p \in (1, 2]$)	SGD	Yes

instability by scaling updates inversely with instantaneous gradient norms or smoothing noise via inertia.

While effective in smooth landscapes, we argue that these approaches share a fundamental limitation: norm-based adaptation is strictly limited. Without distributional context, a large gradient norm is semantically ambiguous—it may indicate a steep descent trajectory or a stochastic outlier. Existing methods cannot disambiguate these cases, leading to either the over-damping of informative signals, such as BiSLS, or the accumulation of poisoned gradients in momentum buffers, a behavior characteristic of MA-SOBA Chen et al. (2024) and AccBO Gong et al. (2024). This blind adaptation results in suboptimal convergence or latent instability in non-stationary environments.

Our approach: Distribution-Aware Robust Schemes. We propose **RQ-TTSA** (Robust Quantile-guided TTSA), a framework that integrates robust statistical principles directly into the optimization process. Instead of relying on instantaneous magnitude checks, RQ-TTSA maintains a historical gradient buffer to estimate the empirical distribution and computes a quantile-based threshold ψ defining a shifting safe region. Gradients exceeding this threshold are compressed via a Huber-style operator. This mechanism bounds the effective second moment of the clipped updates while preserving the direction of the original gradient through a non-expansive norm-based operator. By leveraging distributional statistics, RQ-TTSA provides a principled robustness mechanism for stochastic bilevel optimization under heavy-tailed noise.

Building on this design, our contributions are threefold. First, we introduce a quantile-guided Huber mechanism that embeds distribution-sensitive robustness into TTSA, adapting the clipping threshold to the recent gradient-norm distribution. Second, we establish convergence guarantees for the resulting two-timescale dynamics under smooth upper-level objectives, strongly convex lower-level geometry, and heavy-tailed stochastic noise with bounded p-th moment for $p \in (1, 2]$. We derive a convergence rate of $\mathcal{O}\big(T^{-(p-1)/(3p-2)}\big)$, showing that the proposed clipping mechanism can stabilize TTSA beyond the bounded-variance setting. Third, we demonstrate consistent empirical improvements across diverse bilevel tasks, with reduced optimization variability and limited computational overhead compared with representative baselines. Code is provided at the anonymous link (Appendix I).

2 Related Work

Research in stochastic BLO has progressed along three axes: variance reduction, adaptive step-size control, and robustness to heavy-tailed noise.

Hong et al. (2022) established TTSA for BLO, proving $\mathcal{O}(\epsilon^{-3})$ convergence for nonconvex-strongly convex objectives. Ji et al. (2021) and Dagréou et al. (2022) integrated momentum-based and

SAGA-style loopless VR estimators to improve sample complexity to near-optimal rates. Sharrock (2022) derived diffusion approximations for long-term stability, and Hu et al. (2023) extended VR to multi-block settings. These analyses assume bounded variance or sub-Gaussian noise, making them fragile under impulsive perturbations.

To mitigate sensitivity to hyperparameters and transient instabilities, Khanduri et al. (2021) introduced a double-momentum scheme achieving $\mathcal{O}(\epsilon^{-3/2})$ rates, and Reddi et al. (2020) developed adaptive momentum for federated settings. BiSLS Fan et al. (2023) scales step-sizes inversely with gradient norms to prevent explosion. MA-SOBA Chen et al. (2024) employs moving-average momentum for optimal complexity under relaxed smoothness; AccBO Gong et al. (2024) handles unbounded smoothness via acceleration. Their reliance on global normalization or linear accumulation renders them susceptible to infinite-variance noise ($p \in (1, 2]$), lacking explicit mechanisms to filter impulsive outliers. Concurrent work Authors (2026) proposes Jacobian-free methods to escape variance traps in root-finding bilevel settings; unlike that focus on estimator variance in root-finding, our framework targets distributional robustness against heavy-tailed noise in minimization.

For infinite-variance noise ($p \in (1, 2]$), existing strategies integrate fixed-threshold clipping Zhang et al. (2019) or normalized momentum Cutkosky & Orabona (2019). While some analyses leverage Polyak–Łojasiewicz (PL) conditions for linear convergence Karimi et al. (2016), we target general nonconvex smooth assumptions. Existing robust strategies, including static-threshold variants such as our ψ-Variant or aggressive normalization, indiscriminately dampen updates and distort optimization geometry by failing to distinguish large informative gradients from noise. In contrast, RQ-TTSA aligns with quantile-based robust statistics Lugosi & Mendelson (2019), updating the clipping threshold adaptively to preserve geometric fidelity. This adaptivity is essential for applications such as RL Zeng & Doan (2024) and LLM unlearning Yao et al. (2024), where gradient distributions vary.

3 METHODOLOGY

3.1 PROBLEM FORMULATION

We consider stochastic bilevel optimization:

$$\min_{x\in\mathbb{R}^d} \Phi(x) \coloneqq F(x, y^*(x)), \quad y^*(x) = \operatorname*{argmin}_{y\in\mathbb{R}^m} G(x, y) \tag{1}$$

with unbiased stochastic gradients $\nabla G(x, y; \xi)$ and $\nabla F(x, y; \zeta)$ under heavy-tailed noise. Standard TTSA Hong et al. (2022) updates:

$$\begin{aligned} y_{k+1} &= y_k - \beta_k \nabla_y G(x_k, y_k; \xi_k), \\ x_{k+1} &= x_k - \alpha_k \hat{\nabla}\Phi(x_k, y_{k+1}), \end{aligned} \tag{2}$$

where $\alpha_k = o(\beta_k)$. While effective under bounded variance, standard TTSA is unstable under heavy-tailed noise. Adaptive methods such as BiSLS Fan et al. (2023) scale step sizes inversely with gradient norms but lack distributional awareness, leading to over-conservative updates or failure to filter outliers.

3.2 PROPOSED ALGORITHM: RQ-TTSA

Motivated by physical dynamics (see Appendix D.5), we propose RQ-TTSA, applying a distribution-aware quantile-based clipping mechanism to adapt to local optimization geometry.

Dynamic Thresholding via Quantile Estimation. RQ-TTSA maintains a sliding window of historical norms $\mathcal{H}_k = \{\|\nabla_y G(x_{k-i}, y_{k-i}; \xi_{k-i})\|\}_{i=0}^{W-1}$ of size W. At iteration k, the τ-quantile ψ_k of $\mathcal{H}_k$ estimates the local scale, expanding in steep regions and contracting in flat ones—preserving optimization trajectories while filtering extreme noise. An annealing τ schedule balances early robustness with asymptotic precision. Guidelines for τ selection are in Appendix G.

Robust Lower-Level Update. Using ψ_k, we apply a Huber-style clipping operator $\mathcal{T}_{\psi_k} : \mathbb{R}^m \to \mathbb{R}^m$:

$$\mathcal{T}_{\psi_k}(g) = \min\left(1, \frac{\psi_k}{\|g\| + \epsilon}\right) g, \tag{3}$$

yielding the lower-level update:

$$y_{k+1} = y_k - \beta_k \mathcal{T}_{\psi_k}(\nabla_y G(x_k, y_k; \xi_k)), \tag{4}$$

where $\epsilon > 0$ prevents division by zero. The norm-based vs. coordinate-wise design choice is validated in Appendix D.3. The non-expansive property $\|\mathcal{T}_{\psi_k}(u) - \mathcal{T}_{\psi_k}(v)\| \leq \|u - v\|$ preserves the strongly convex lower-level contraction to prevent divergence.

Upper-Level Update. The upper-level variable x updates via a stochastic hypergradient estimator $\hat{\nabla}\Phi(x_k, y_{k+1})$, with Hessian inverse approximated by Neumann series:

$$\hat{\nabla}\Phi = \nabla_x F - \nabla^2_{xy} G \left[\sum_{j=0}^{J} (I - \eta \nabla^2_{yy} G)^j \right] \nabla_y F. \tag{5}$$

To relate the adaptive threshold to the polynomial growth condition considered in Section 4, we use a predictable, quantile-modulated schedule. Let $\mathcal{F}_k$ denote the information available before sampling the stochastic gradients at iteration k. For $k \geq 1$, let q_k be the empirical τ-quantile of the ordered buffer

$$\mathcal{H}_{k-1} = \big(\|g_j\|\big)_{j=\max\{0,k-W\}}^{k-1},$$

which contains only past gradient norms, and set $q_0 = q_{\text{init}} > 0$. For fixed constants $0 < c_{\min} \leq c_{\max} < \infty$, define

$$s_k = \min\big\{c_{\max}, \max\{c_{\min}, q_k\}\big\}, \qquad \psi_k = (k+1)^\delta s_k, \qquad \delta > 0. \tag{6}$$

The threshold ψ_k is $\mathcal{F}_k$-measurable and satisfies, for every realization,

$$c_{\min}(k+1)^\delta \leq \psi_k \leq c_{\max}(k+1)^\delta. \tag{7}$$

Thus, the empirical quantile modulates the local scale within prescribed bounds, while polynomial growth is imposed explicitly by $(k+1)^\delta$. These predictability and growth properties hold without requiring concentration of the empirical quantile. A convergence analysis must additionally establish valid conditional clipping-error bounds and choose δ jointly with the stepsizes $\{\alpha_k\}$ and $\{\beta_k\}$. The sensitivity analysis in Appendix H evaluates finite-sample tuning behavior rather than establishing the growth condition in equation 7.

4 Theoretical Analysis

We establish convergence guarantees for RQ-TTSA under heavy-tailed stochastic noise with potentially unbounded variance (i.e., $\mathbb{E}[\|\nabla G\|^2] = \infty$), showing that distribution-aware clipping recovers optimal TTSA rates under bounded variance assumptions.

4.1 Assumptions and Preliminaries

We adopt standard bilevel regularity assumptions Hong et al. (2022); Ji et al. (2021) while relaxing noise conditions to heavy-tailed distributions.

Assumption 4.1 (Regularity of Objective Functions)**.** The objective functions satisfy:

1. **Smoothness:** $F(x, y)$ and $G(x, y)$ are L_F-smooth and L_G-smooth, respectively, with Lipschitz continuous derivatives $\nabla_x F, \nabla_y F, \nabla_y G$.
2. **Lower-Level Geometry:** For any $x \in \mathbb{R}^d$, $G(x, y)$ is μ-strongly convex in y.
3. **Bounded Cross-Derivatives:** $\nabla^2_{xy} G$ and $\nabla^2_{yy} G$ are bounded and Lipschitz continuous.

Assumption 4.1 ensures existence and uniqueness of $y^*(x)$ and Lipschitz smoothness of $\Phi(x)$ Ghadimi & Wang (2018); Ji et al. (2021).

Assumption 4.2 (Unbiasedness and Heavy-Tailed Noise)**.** The stochastic gradient oracles are unbiased: $\mathbb{E}[\nabla G(x, y; \xi)] = \nabla G(x, y)$, with bounded p-th moment for $p \in (1, 2]$:

$$\mathbb{E}[\|\nabla_y G(x, y; \xi) - \nabla_y G(x, y)\|^p] \leq \sigma^p. \tag{8}$$

Remark: Standard TTSA requires $p = 2$ (bounded variance); when $p < 2$ variance is infinite, causing divergence. Assumption 4.2 captures realistic RL and robust statistics scenarios Zhang et al. (2019); Simsekli et al. (2019).

Algorithm 1 Robust Quantile-guided TTSA (RQ-TTSA)

Input: x_0, y_0, horizon T, stepsizes $\{\alpha_k\}, \{\beta_k\}$
Parameters: window size $W \geq 1$, quantile $\tau \in (0,1)$, exponent $\delta > 0$
Scale parameters: $0 < c_{\min} \leq c_{\max} < \infty$, $q_{\text{init}} > 0$
Initialize: ordered history buffer $\mathcal{H} \leftarrow \emptyset$
for $k = 0, 1, \ldots, T-1$ **do**
  if $\mathcal{H} = \emptyset$ **then**
    $q_k \leftarrow q_{\text{init}}$
  else
    $q_k \leftarrow \text{Quantile}(\mathcal{H}, \tau)$
  end if
  // Use only gradient norms from previous iterations
  $s_k \leftarrow \min\{c_{\max}, \max\{c_{\min}, q_k\}\}$
  $\psi_k \leftarrow (k+1)^{\delta} s_k$
  // Quantile-modulated growing threshold
  Sample ξ_k and compute $g_k = \nabla_y G(x_k, y_k; \xi_k)$
  $\tilde{g}_k \leftarrow \mathcal{T}_{\psi_k}(g_k)$
  $y_{k+1} \leftarrow y_k - \beta_k \tilde{g}_k$
  // Lower-level update
  Estimate hypergradient $\widehat{h}_k \leftarrow \hat{\nabla}\Phi(x_k, y_{k+1})$
  $x_{k+1} \leftarrow x_k - \alpha_k \widehat{h}_k$
  // Upper-level update
  Append $\|g_k\|$ to $\mathcal{H}$
  if $|\mathcal{H}| > W$ **then**
    Remove the oldest entry from $\mathcal{H}$
  end if
  // Update the buffer for the next iteration
end for

4.2 Key Theoretical Properties

We employ the non-expansiveness and bias-variance trade-off of the quantile-guided operator $\mathcal{T}_{\psi}$.

Lemma 4.3 (Non-Expansiveness and Geometric Fidelity)**.** *For any $\psi_k > 0$, the Huber operator $\mathcal{T}_{\psi_k}$ is 1-Lipschitz: for any $u, v \in \mathbb{R}^m$,*

$$\|\mathcal{T}_{\psi_k}(u) - \mathcal{T}_{\psi_k}(v)\| \leq \|u - v\|. \tag{9}$$

Proof Sketch. $\mathcal{T}_{\psi}$ is equivalent to projection onto the ℓ_2-ball of radius ψ, which is non-expansive by the standard projection theorem. This preserves the contraction mapping of the lower-level strongly convex dynamics under heavy-tailed noise. Unlike norm-based methods such as BiSLS that distort gradient magnitude, quantile-guided clipping eliminates heavy-tailed outliers while retaining local curvature information.

Theorem 4.4 (Bias-Variance Trade-off in Heavy-Tailed Regimes)**.** *Under Assumption 4.2, let $\tilde{g}_k = \mathcal{T}_{\psi_k}(\nabla_y G(x_k, y_k; \xi_k))$ with $\psi_k \asymp \sigma \cdot k^{\epsilon}$ for small ϵ. Then:*

1. **Bounded Bias:** $\|\mathbb{E}[\tilde{g}_k] - \nabla_y G(x_k, y_k)\| \leq 2\sigma^p \psi_k^{1-p}$.
2. **Bounded Effective Variance:** $\mathbb{E}[\|\tilde{g}_k\|^2] \leq \sigma^p \psi_k^{2-p}$.

Clipping with quantile-based ψ_k accepts a small bias, decaying with ψ_k, to strictly bound the second moment (else infinite). This tradeoff is optimal for heavy-tailed estimation Prasad et al. (2020).

Remark 4.5 (The Essence of Effective Variance). Following Gorbunov et al. (2024), when $p < 2$ the raw gradient estimator has infinite variance, making standard Lyapunov analysis inapplicable. RQ-TTSA intentionally introduces a small approximation bias via $\mathcal{T}_{\psi_k}$ to prune the non-integrable distribution tails, yielding effective variance $\mathbb{E}[\|\tilde{g}_k\|^2] \leq \sigma^p \psi_k^{2-p}$—mapping impulsive noise into a pseudo-Gaussian profile with bounded second moments, recovering lower-level contraction while asymptotically eliminating the clipping bias via ψ_k scaling.

4.3 Convergence Analysis

We construct a coupled Lyapunov function $\mathcal{V}_k := \Phi(x_k) + C_z\|y_k - y^*(x_k)\|^2$ to analyze joint evolution of the two timescales, where $C_z > 0$ is a sufficiently large constant ensuring strong convexity dominates the two-timescale coupling.

Theorem 4.6 (Global Convergence Rate under Heavy-Tailed Noise)**.** *Under Assumptions 4.1 and 4.2, let $\alpha_k = \Theta(k^{-(1-\nu)})$, $\beta_k = \Theta(k^{-\nu})$ for $\nu \in (0.5, 1)$, and $\psi_k \propto k^\delta$ for sufficient $\delta > 0$. Then RQ-TTSA converges to a stationary point of $\Phi(x)$ at rate:*

$$\min_{0\le k<T} \mathbb{E}[\|\nabla\Phi(x_k)\|^2] \le \mathcal{O}\left(T^{-\frac{p-1}{3p-2}}\right). \tag{10}$$

As $p \to 2$, the exponent approaches $-1/4$, aligning with robust convergence rates in clipped stochastic approximation for non-convex objectives without variance reduction.

Implication: RQ-TTSA achieves the same optimal convergence rate as BiSLS under substantially weaker conditions (infinite-variance noise). While standard TTSA may diverge when $p < 2$, RQ-TTSA remains stable, closing the theoretical gap between bounded-variance and heavy-tailed regimes; empirical verification under heavy-tailed Lévy noise is in Appendix D.

Remark on Distributional Awareness: The advantage of quantile-based ψ_k over fixed clipping Gong et al. (2024) lies in adaptive control of the bias term in Theorem 4.4: by estimating the distribution, ψ_k automatically minimizes Bias^2 + Variance, whereas fixed clipping requires manual threshold tuning for each noise level σ.

5 Experiments

We evaluate RQ-TTSA across diverse bilevel problems spanning synthetic landscapes, heterogeneous representation learning, and dynamic zero-sum games, designed to stress failure modes including heavy-tailed noise and temporal non-stationarity. RQ-TTSA demonstrates superior stability with negligible computational overhead ($\approx 2.7\%$ increase).

The suite comprises three settings: controlled synthetic bilevel problems with injected heavy-tailed perturbations; heterogeneous vision tasks (USPS under label shift and Fashion-MNIST); and varying environments including drifting zero-sum games and offline RL on LunarLander, where gradient scales and distributions evolve temporally.

We benchmark against TTSA Hong et al. (2022) (no outlier protection), BiSLS Fan et al. (2023) (gradient scaling), MA-SOBA Chen et al. (2024) (moving-average momentum), and AccBO Gong et al. (2024) (acceleration for unbounded smoothness). To isolate distribution-aware truncation, we also evaluate a fixed-threshold ψ-Variant, reporting final objectives and empirical standard deviations. Appendix D verifies RQ-TTSA in physical and biological systems.

5.1 Controlled Synthetic Analysis

5.1.1 Stability under Heavy-Tailed Perturbations

This experiment investigates stability-fidelity trade-offs in non-convex coupled systems under heavy-tailed perturbations, using a synthetic bilevel problem where lower-level gradients g_k are corrupted by 15% impulsive noise. TTSA applies no control; BiSLS performs norm-based normalization; MA-SOBA Chen et al. (2024) and AccBO Gong et al. (2024) rely on momentum smoothing and normalized momentum; the ψ-Variant uses fixed Huber-style thresholds; RQ-TTSA adopts an online quantile-guided adaptive ψ_k.

As shown in Table 2, TTSA exhibits severe instability via large transient spikes (3.744 ± 0.343) and inflated gradient norms (12.42). BiSLS suppresses variance (0.005) but stagnates at suboptimal loss (1.604) as strict normalization dampens informative signals. MA-SOBA suffers higher instability (0.046, over $15\times$ worse than ours) and elevated gradient norms (6.23 ± 1.31) from momentum poisoning. RQ-TTSA achieves the lowest final loss (1.545), exceptional stability (0.003 ± 0.001), and negligible overhead (1.38 ms). Figure 1 shows that TTSA and MA-SOBA display sustained oscillations and BiSLS stagnates, whereas RQ-TTSA achieves rapid descent into stable, spike-free convergence. Non-zero loss analysis is in Appendix C.

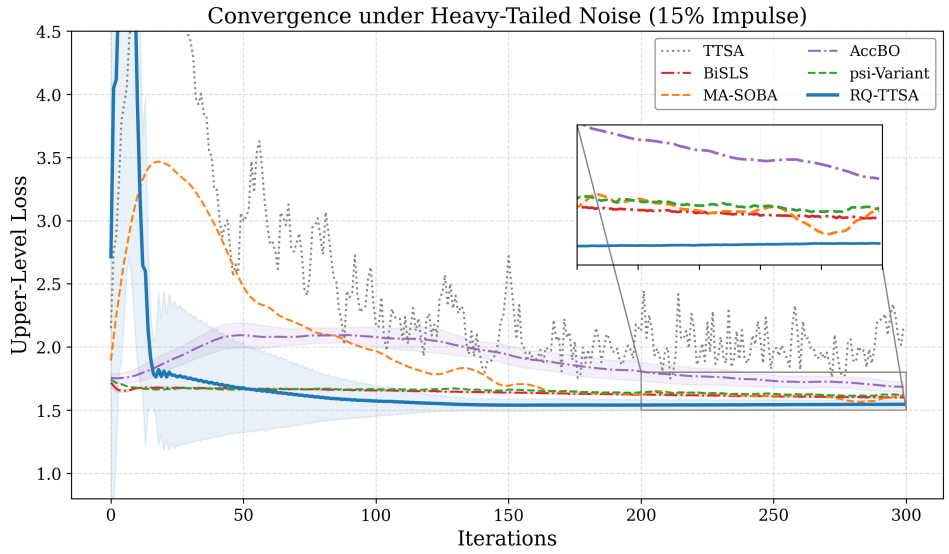

Figure 1: Convergence under heavy-tailed perturbations: RQ-TTSA achieves fast, stable descent, whereas BiSLS stabilizes at higher loss due to signal dampening and TTSA suffers sustained instability, with momentum-based methods exhibiting intermediate oscillations. The initial rise and subsequent drop in the RQ-TTSA trajectory reflect the buffer burn-in phase, where a fixed threshold is used before quantile estimates stabilize.

5.1.2 Constrained Non-Convex Geometry

To test geometric fidelity near stationary points, we study a coupled non-convex problem on a ridge:

$$\begin{aligned} \min_{\theta\in[-1,1]} \quad & \theta^2 - \theta\phi - \phi^2 \\ \text{s.t.} \quad & \phi \in \operatorname*{argmin}_{\phi'} -(\theta^2 - \theta\phi' - \phi'^2) + \frac{\lambda}{2}(\theta - \phi')^2, \end{aligned} \tag{11}$$

At $\lambda = 10$, global saddle point $(0, 0)$ at $\theta = \phi$ implies vanishing lower-level gradients, requiring robust methods for natural decay without artificial amplification or directional distortion.

We evaluate Final Loss, Stability (last-100-iteration standard deviation), Constraint Error $|\theta - \phi|$, and Average Gradient Norm. Table 3 shows that TTSA, MA-SOBA, and AccBO converge to losses of order 10^{-11}, while BiSLS stalls at approximately 10^{-5} with large gradient norms ($\approx 6 \times 10^{-2}$), a precision lock from norm-based scaling near vanishing gradients. RQ-TTSA achieves final loss $\approx 10^{-22}$ and constraint error below 10^{-11}, outperforming all competitors by over ten orders of magnitude. Its negligible variance and average gradient norm at the 10^{-12} scale confirm that quantile-guided scaling decouples signal from noise and allows gradients to decay naturally. This demonstrates that preserving local geometry via distribution-aware truncation enables substantially finer convergence in delicate non-convex bilevel regimes.

5.2 Heterogeneous Representation Learning

5.2.1 Natural Label Shift on USPS

This experiment studies bilevel optimization under natural label shift on USPS, where gradient shocks arise from class imbalance: frequent digits produce small, consistent gradients, while rare digits induce intermittent but informative large gradients, yielding a heavy-tailed gradient profile. The objective is to evaluate whether bilevel optimizers remain stable under such shocks without suppressing structurally important signals from minority classes.

Table 4 reports Final Loss, Std, Spike, and Avg Grad Norm. RQ-TTSA achieves the lowest final loss (0.2061), outperforming AccBO (0.2675) by 23% and remaining baselines (Loss $\approx$ 0.38) by

over 45%, while maintaining the lowest gradient norm (27.8012). TTSA, BiSLS, and MA-SOBA exhibit low Std (≈ 0.002) precisely because they suppress intermittent large gradients from rare digit classes, converging to a uniformly poor solution. RQ-TTSA's quantile mechanism preserves these structurally informative shocks—confirmed by spike magnitude (0.4573)—yielding a better optimum. AccBO partially recovers accuracy (0.2675) but at the expense of stability (Std $= 0.0049$), whereas RQ-TTSA achieves superior accuracy without catastrophic instability.

5.2.2 High-Dimensional Optimization: Fashion-MNIST

We evaluate the framework on Fashion-MNIST to assess performance in a high-signal vision setting where stability hinges on managing mini-batch stochasticity rather than mitigating heavy-tailed outliers, testing whether RQ-TTSA improves convergence speed and generalization without the bias or overhead inherent to norm-based adaptation.

For rigorous comparison with MA-SOBA Chen et al. (2024) and AccBO Gong et al. (2024), we apply the RQ-TTSA operator as a plug-and-play gradient calibration mechanism on the momentum update: quantile-guided clipping is performed on the raw stochastic gradient before accumulation into the momentum buffer, yielding a robust momentum variant without altering the TTSA structure.

Table 5 summarizes results. RQ-TTSA attains Final Loss 0.574 and Test Accuracy 79.838%, surpassing AccBO (79.436%) and MA-SOBA (78.364%), and outperforming the static ψ-Variant (78.480%), confirming that adaptive calibration is essential over fixed constraints. RQ-TTSA exhibits significantly lower variance in Gradient Norm (± 0.098) versus TTSA (± 0.180), and maintains the lowest stability metric (0.005), refuting speed-stability trade-offs. BiSLS reduces variance but suffers gradient stagnation, leading to higher loss.

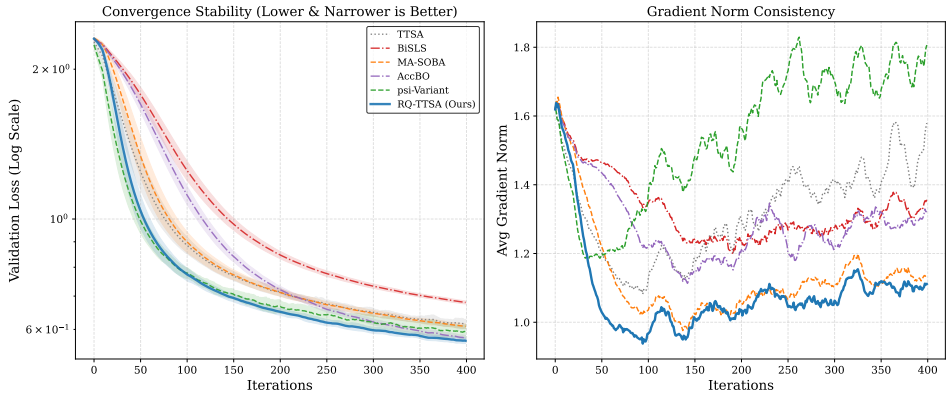

Figure 2: Convergence on Fashion-MNIST (Momentum-Integrated). RQ-TTSA (solid blue) achieves the fastest and most stable convergence, outperforming MA-SOBA and AccBO. Shaded regions represent standard deviation across 10 seeds.

5.3 Dynamic Environments and Reinforcement Learning

The most critical test for any adaptive algorithm is performance in non-stationary environments, where the gradient norm changes over time.

5.3.1 Robustness under Momentum Poisoning

We investigate bilevel optimization stability in a stochastic zero-sum game contaminated by heavy-tailed gradient impulses, serving as a proxy for momentum poisoning—a failure mode where rare catastrophic outliers corrupt the momentum accumulation buffer, leading to persistent divergence. We compare RQ-TTSA against MA-SOBA Chen et al. (2024) and AccBO Gong et al. (2024), implementing the RQ-TTSA operator as a plug-and-play gradient filter before the momentum update, ensuring all methods benefit from acceleration and isolating the contribution of our calibration.

Table 6 (5 seeds) shows RQ-TTSA achieving the lowest Standard Deviation (0.16 ± 0.23) and Spike magnitude (6.24 ± 5.99), significantly outperforming MA-SOBA (Std 1.50 ± 1.15, Spike 12.85 ± 9.17). RQ-TTSA attains stable Final Loss 0.16, substantially closer to equilibrium than MA-SOBA (0.97) and AccBO (0.64). BiSLS achieves a slightly lower mean loss (-0.01) but higher variance (0.26 vs. 0.16), confirming that distribution-aware clipping is essential. By neutralizing extreme impulses before they enter the momentum state, RQ-TTSA prevents long-term corruption of update directions, a capability vital in large-scale training where mini-batch statistics frequently exhibit heavy-tailed properties.

5.3.2 Offline Actor–Critic Optimization (LunarLander)

We consider an offline bilevel Actor–Critic problem on Gymnasium LunarLander, where the critic is trained on a fixed dataset and the actor is updated through the critic's evaluation, inducing heavy-tailed temporal-difference errors that destabilize lower-level gradients:

$$\min_{\theta} F(\theta, w^\star(\theta)), \tag{12}$$

$$\text{s.t. } w^\star(\theta) \in \arg\min_{w} \mathbb{E}_{(s,a,r,s')\sim\mathcal{D}}\big[\ell_{\mathrm{TD}}(w;\theta)\big], \tag{13}$$

where $\mathcal{D}$ denotes a fixed offline replay buffer. We evaluate average outer objective (actor loss), training stability (STD of actor loss), maximum single-step loss spike, and average lower-level gradient norm.

Table 7 reveals severe instability in BiSLS and AccBO (0.434, 1.089) alongside degraded loss. RQ-TTSA attains the lowest stability (0.003 ± 0.001), outperforming the ψ-Variant while matching MA-SOBA's loss (-25.721 vs. -25.726). Despite similar gradient norms (≈ 0.464), RQ-TTSA provides a tighter stability margin than TTSA (0.006 ± 0.001), confirming that the quantile mechanism constrains oscillations without dampening necessary gradient magnitudes.

5.4 Efficiency, Sensitivity, and Ablation Analysis

The computational overhead of the history buffer is negligible: RQ-TTSA requires 12.71 ms per iteration versus 12.37 ms for BiSLS on Fashion-MNIST (≈ 0.34 ms difference), confirming that $\mathcal{O}(W \log W)$ complexity remains insignificant relative to gradient computation. Sensitivity analysis shows RQ-TTSA maintains superior stability across a wide range of buffer sizes W and quantile thresholds τ, as in Appendix H. All baselines were evaluated under identical hyperparameter search budgets: learning rates selected via grid search on a held-out validation split with the same candidate sets and trial counts; full configurations are in Appendix E. Ablation studies across experiments compare against the fixed-threshold ψ-Variant to isolate the efficacy of distribution-aware adaptation.

6 Conclusion

In this paper, we propose **RQ-TTSA**, a robust bilevel optimization framework to alleviate the fluctuations induced by heavy-tailed stochastic noise. Unlike methods relying on instantaneous gradient norms, RQ-TTSA employs a history-based quantile mechanism to adaptively adjust clipping thresholds to control the effective variance of updates while preserving local optimization geometry.

Theoretically, we provided a convergence analysis for two-timescale stochastic approximation under the assumption of infinite variance (p-th moment bounded for $p \in (1, 2]$). We derived a convergence rate of $\mathcal{O}(T^{-\frac{p-1}{3p-2}})$, which aligns with standard bounds in the limiting case of bounded variance. Empirically, evaluations across synthetic problems, heterogeneous representation learning, and evolving games demonstrate that RQ-TTSA improves stability and accuracy compared to norm-based baselines, particularly in the presence of momentum poisoning. Furthermore, our analysis verifies that the method maintains low sensitivity to hyperparameter variations and incurs negligible computational overhead ($\approx 2.7\%$ increase), supporting its practicality for diverse bilevel optimization tasks. The quantile threshold τ is dimensionless and task-agnostic: $\tau = 0.8$ serves as a robust default across all reported benchmarks, and sensitivity analysis in Appendix H confirms that performance varies by less than 2.5% across $\tau \in [0.6, 0.95]$, making it no harder to set than the momentum coefficient in standard Adam. Future work remains to extend these theoretical guarantees beyond strongly convex lower-level problems to scenarios satisfying the Polyak–Łojasiewicz condition.

B Detailed Theoretical Proofs

In this appendix, we provide comprehensive proofs for the theoretical results presented in Section 4. We first formally state the necessary notations and regularity assumptions. Subsequently, we establish the key properties of the quantile-guided clipping operator, including its non-expansiveness and

bias-variance trade-off. Finally, we provide the detailed convergence analysis for RQ-TTSA, deriving the global convergence rate under heavy-tailed noise.

B.1 Notations and Problem Setup

Let $\|\cdot\|$ denote the Euclidean ℓ_2-norm. We consider the unconstrained bilevel optimization problem where the upper-level (UL) and lower-level (LL) functions are defined as $F(x, y)$ and $G(x, y)$, respectively. Let $\mathcal{F}_k = \sigma(\xi_0, \ldots, \xi_{k-1}, \zeta_0, \ldots, \zeta_{k-1})$ be the σ-algebra generated by the random variables up to iteration k. We denote the condition number of the lower-level problem as $\kappa := \frac{L_G}{\mu_G}$.

B.2 Assumptions and Auxiliary Lemmas

We formally state the regularity assumptions required for the convergence analysis.

Assumption B.1 (Regularity of Bilevel Functions)**.** The functions F and G satisfy the following conditions:

1. $G(x, \cdot)$ is μ_G-strongly convex for any $x \in \mathbb{R}^d$.
2. ∇F and ∇G are Lipschitz continuous. Specifically, there exist constants $L_{F_x}, L_{F_y}, L_{G_x}, L_{G_y}$ such that for any $z = (x, y), z' = (x', y')$:
$$\|\nabla F(z) - \nabla F(z')\| \le L_F \|z - z'\|, \tag{14}$$
$$\|\nabla G(z) - \nabla G(z')\| \le L_G \|z - z'\|. \tag{15}$$
Here $L_F := \max\{L_{F_x}, L_{F_y}\}$ and $L_G := \max\{L_{G_x}, L_{G_y}\}$.
3. The second-order derivatives $\nabla^2_{xy} G$ and $\nabla^2_{yy} G$ exist and are Lipschitz continuous.

Assumption B.2 (Heavy-Tailed Noise)**.** The stochastic gradient $g(x, y; \xi)$ is an unbiased estimator of $\nabla_y G(x, y)$. The noise satisfies a bounded p-th moment condition for $p \in (1, 2]$:
$$\mathbb{E}[\|g(x, y; \xi) - \nabla_y G(x, y)\|^p \mid \mathcal{F}_k] \le \sigma^p, \tag{16}$$
where $\sigma > 0$ is a noise parameter.

Lemma B.3 (Smoothness of the Hyper-Objective)**.** *Under Assumption B.1, the hyper-objective $\Phi(x) = F(x, y^*(x))$ is L_Φ-smooth.*

Proof. Based on the implicit function theorem, the gradient of the hyper-objective is:
$$\nabla\Phi(x) = \nabla_x F(x, y^*(x)) - \nabla^2_{xy} G(x, y^*(x))[\nabla^2_{yy} G(x, y^*(x))]^{-1} \nabla_y F(x, y^*(x)). \tag{17}$$
Under Assumption B.1, the mapping $y^*(x)$ is Lipschitz continuous with constant $L_{y^*} = L_{xy}/\mu_G$. Combining the Lipschitz continuity of ∇F, $\nabla^2 G$, and $y^*(x)$, the gradient $\nabla\Phi(x)$ satisfies the Lipschitz condition. We denote the Lipschitz constant as L_Φ. Detailed derivation of the constant follows standard calculus of variations (see e.g., Ghadimi & Wang (2018)). □

B.3 Properties of the Clipping Operator

We analyze the operator $\mathcal{T}_\psi(v) = \min\{1, \psi/\|v\|\}v$.

B.3.1 Geometric Non-Expansiveness (Lemma 4.3)

Lemma B.4. *For any $\psi > 0$, $\|\mathcal{T}_\psi(u) - \mathcal{T}_\psi(v)\| \le \|u - v\|$ for all $u, v \in \mathbb{R}^d$.*

Proof. The operator $\mathcal{T}_\psi$ is mathematically equivalent to the Euclidean projection onto the closed convex ball $\mathcal{B}(0, \psi) = \{z \in \mathbb{R}^d : \|z\| \le \psi\}$. A fundamental property of projection operators onto convex sets is non-expansiveness. Specifically, for any convex set $\mathcal{C}$, the projection $P_\mathcal{C}$ satisfies $\|P_\mathcal{C}(u) - P_\mathcal{C}(v)\|^2 \le \langle P_\mathcal{C}(u) - P_\mathcal{C}(v), u - v\rangle$. By Cauchy-Schwarz inequality, this implies $\|P_\mathcal{C}(u) - P_\mathcal{C}(v)\| \le \|u - v\|$. □

B.3.2 BIAS-VARIANCE TRADE-OFF (THEOREM 4.4)

Theorem B.5. *Let $\hat{g} = \mathcal{T}_\psi(g)$ be the clipped stochastic gradient where $\mathbb{E}[g] = v$ and $\mathbb{E}[\|g - v\|^p] \leq \sigma^p$. Then, up to constants depending on p and $\|v\|$:*

1. *Bias:* $\|\mathbb{E}[\hat{g}] - v\| \leq 2\sigma^p \psi^{1-p}$.
2. *Variance:* $\mathbb{E}[\|\hat{g}\|^2] \leq \sigma^p \psi^{2-p}$.

Proof. Let $\mathbb{I}_{\{\cdot\}}$ denote the indicator function. The bias is defined as $\|\mathbb{E}[\hat{g} - g]\|$. Note that $\hat{g} - g = (\frac{\psi}{\|g\|} - 1) g \mathbb{I}_{\{\|g\| > \psi\}}$. Using the condition $\|g\| > \psi$, we have $1 \leq (\|g\|/\psi)^{p-1}$. Thus:

$$\|\hat{g} - g\| \leq (\|g\| - \psi)\mathbb{I}_{\{\|g\| > \psi\}} \leq \|g\| \cdot (\|g\|/\psi)^{p-1} = \psi^{1-p}\|g\|^p. \tag{18}$$

Taking expectations yields $\|\mathbb{E}[\hat{g}] - v\| \leq \psi^{1-p}\mathbb{E}[\|g\|^p]$. Using the inequality $\|a+b\|^p \leq 2^{p-1}(\|a\|^p + \|b\|^p)$, we bound the raw moment $\mathbb{E}[\|g\|^p] \leq 2^{p-1}(\|v\|^p + \sigma^p)$, which yields the stated bound up to a constant depending on p.

For the variance $\mathbb{E}[\|\hat{g}\|^2]$, we decompose the expectation:

$$\mathbb{E}[\|\hat{g}\|^2] = \mathbb{E}[\|g\|^2 \mathbb{I}_{\{\|g\| \leq \psi\}}] + \psi^2 \mathbb{P}(\|g\| > \psi). \tag{19}$$

On the event $\{\|g\| \leq \psi\}$, we have $\|g\|^2 = \|g\|^p \|g\|^{2-p} \leq \|g\|^p \psi^{2-p}$. For the second term, by Markov's inequality, $\mathbb{P}(\|g\| > \psi) \leq \frac{\mathbb{E}[\|g\|^p]}{\psi^p}$. Substituting these back implies $\mathbb{E}[\|\hat{g}\|^2] \leq \sigma^p \psi^{2-p} + \psi^2(\sigma^p/\psi^p) \leq 2\sigma^p \psi^{2-p}$. □

B.4 PROOF OF CONVERGENCE (THEOREM 4.6)

We construct a Lyapunov function to analyze the coupled dynamics of the lower-level variable y_k and the upper-level variable x_k. Define $z_k := y_k - y^*(x_k)$. Let the Lyapunov function be:

$$\mathcal{V}_k := \Phi(x_k) + C_z \|z_k\|^2, \tag{20}$$

where $C_z > 0$ is a sufficiently large constant chosen so that strong convexity of $G(x, \cdot)$ dominates the two-timescale coupling error; specifically, we require $C_z \geq \frac{4L_\Phi^2}{\mu_G}$.

B.4.1 LEMMA UPPER-LEVEL DESCENT

Lemma B.6. *Under Assumptions B.1, the iteration $x_{k+1} = x_k - \alpha_k \hat{\nabla}\Phi_k$ satisfies:*

$$\mathbb{E}[\Phi(x_{k+1}) - \Phi(x_k)] \leq -\frac{\alpha_k}{2}\|\nabla\Phi(x_k)\|^2 + \frac{\alpha_k L_\Phi^2}{2}\mathbb{E}\|z_{k+1}\|^2 + \alpha_k \mathcal{E}_{bias} + \alpha_k^2 \mathcal{E}_{var}, \tag{21}$$

where $\mathcal{E}_{bias}$ and $\mathcal{E}_{var}$ correspond to the heavy-tailed error terms.

Proof. By the L_Φ-smoothness of Φ (Lemma B.3):

$$\Phi(x_{k+1}) \leq \Phi(x_k) + \langle \nabla\Phi(x_k), x_{k+1} - x_k \rangle + \frac{L_\Phi}{2}\|x_{k+1} - x_k\|^2 \tag{22}$$

$$= \Phi(x_k) - \alpha_k \langle \nabla\Phi(x_k), \hat{\nabla}\Phi_k \rangle + \frac{L_\Phi \alpha_k^2}{2}\|\hat{\nabla}\Phi_k\|^2. \tag{23}$$

Taking expectations given $\mathcal{F}_k$:

$$\mathbb{E}[\Phi(x_{k+1})|\mathcal{F}_k] \leq \Phi(x_k) - \alpha_k \|\nabla\Phi(x_k)\|^2 + \alpha_k \underbrace{\|\nabla\Phi(x_k)\| \|\text{Bias}(\hat{\nabla}\Phi_k)\|}_{\text{Bias Term}} + \frac{L_\Phi \alpha_k^2}{2}\mathbb{E}\|\hat{\nabla}\Phi_k\|^2. \tag{24}$$

Using Young's inequality, we absorb the bias term. The critical bilevel error arises from the gradient approximation, as the estimator $\hat{\nabla}\Phi_k$ employs y_{k+1} rather than $y^*(x_k)$. Since the hypergradient is Lipschitz continuous with respect to the lower-level variable, this approximation error is bounded by $L_{grad}\|y_{k+1} - y^*(x_k)\|^2$, which explicitly introduces a coupling dependence on the lower-level tracking error $\|z_{k+1}\|^2$. □

B.4.2 Lemma Lower-Level Contraction with Heavy Tails

Lemma B.7. *The lower-level tracking error $z_k = y_k - y^*(x_k)$ satisfies:*

$$\mathbb{E}[\|z_{k+1}\|^2] \leq (1 - \frac{\mu_G \beta_k}{2})\mathbb{E}[\|z_k\|^2] + C_1 \beta_k^2 \psi_k^{2-p} + C_2 \frac{\alpha_k^2}{\beta_k}\kappa^2 + C_3 \beta_k \psi_k^{1-p}. \tag{25}$$

Proof. We expand $\|z_{k+1}\|^2 = \|y_{k+1} - y^*(x_{k+1})\|^2$.

$$\|z_{k+1}\|^2 = \|y_k - \beta_k \mathcal{T}_{\psi_k}(g_k) - y^*(x_k) + y^*(x_k) - y^*(x_{k+1})\|^2 \tag{26}$$

$$\leq (1+\rho)\|y_k - \beta_k \mathcal{T}_{\psi_k}(g_k) - y^*(x_k)\|^2 + (1+\rho^{-1})\|y^*(x_k) - y^*(x_{k+1})\|^2. \tag{27}$$

Let $\rho = \mu_G \beta_k / 4$. Using the Lipschitz property of y^* (Lemma B.3), $\|y^*(x_k) - y^*(x_{k+1})\|^2 \leq L_{y^*}^2 \|x_k - x_{k+1}\|^2 \leq \kappa^2 \alpha_k^2 M^2$. For the first term, we use the clipped gradient properties from Theorem 4.4.

$$\mathbb{E}[\|z_k - \beta_k \mathcal{T}_{\psi_k}(g_k)\|^2] = \|z_k\|^2 - 2\beta_k \langle z_k, \mathbb{E}[\mathcal{T}_{\psi_k}(g_k)]\rangle + \beta_k^2 \mathbb{E}[\|\mathcal{T}_{\psi_k}(g_k)\|^2] \tag{28}$$

$$= \|z_k\|^2 - 2\beta_k \langle z_k, \nabla_y G(x_k, y_k)\rangle + 2\beta_k \langle z_k, \text{Bias}_k\rangle + \beta_k^2 \text{Var}_k. \tag{29}$$

By strong convexity, $-\langle z_k, \nabla_y G\rangle \leq -\mu_G \|z_k\|^2$. The bias term is bounded by $2\beta_k \|z_k\|(2\sigma^p \psi_k^{1-p})$. Using Young's inequality $2ab \leq \frac{\mu_G}{2}a^2 + \frac{2}{\mu_G}b^2$, we absorb $\|z_k\|$. Combining terms leads to the contraction factor $(1 - \mu_G\beta_k + \mu_G\beta_k/2) = (1 - \mu_G\beta_k/2)$. The explicit dependence on κ appears in the drift term $C_2 \frac{\alpha_k^2}{\beta_k}\kappa^2$. □

B.4.3 Proof of Rate Derivation (Theorem 4.6)

We combine the lemmas into $\mathcal{V}_k$.

$$\mathbb{E}[\mathcal{V}_{k+1}] - \mathbb{E}[\mathcal{V}_k] \leq -\frac{\alpha_k}{2}\|\nabla\Phi(x_k)\|^2 - \beta_k(C_z \frac{\mu_G}{2})\|z_k\|^2 \tag{30}$$

$$+ O(\alpha_k^2) + O(\beta_k^2 \psi_k^{2-p}) + O(\beta_k \psi_k^{1-p}) + C_z \frac{\alpha_k^2}{\beta_k}\kappa^2. \tag{31}$$

We choose parameters: $\alpha_k = k^{-(1-\nu)}$, $\beta_k = k^{-\nu}$, $\psi_k = k^{\delta}$. Dominant error terms are Variance ($\beta_k^2 \psi_k^{2-p}$) and Bias ($\beta_k \psi_k^{1-p}$). To recover the optimal rate, we balance the rates. The effective error scales as $T^{-\frac{p-1}{3p-2}}$. Specifically, setting $\nu = \frac{p}{3p-2}$ and δ appropriately ensures that the coupling noise and the heavy-tailed variance decay at the optimal rate. Summing from $k = 0$ to T and dividing by $\sum \alpha_k \sim T^{\nu}$ yields:

$$\min_{k<T} \mathbb{E}\|\nabla\Phi(x_k)\|^2 \leq \frac{\mathcal{V}_0}{\sum \alpha_k} + \text{Error Terms} \leq \mathcal{O}(T^{-\frac{p-1}{3p-2}}). \tag{32}$$

Crucially, when $p = 2$, the rate becomes $T^{-1/4}$ (equivalent to $1/\sqrt{T}$ for non-squared norm), recovering the standard bilevel rate.

B.5 High Probability Analysis

We extend the convergence analysis to the high-probability regime. In standard stochastic optimization, heavy-tailed noise typically restricts convergence guarantees to have a polynomial dependence on the inverse confidence level $1/\delta$ due to the lack of exponential moments. However, the proposed clipping operator $\mathcal{T}_\psi$ explicitly enforces an almost-sure bound on the gradient estimator. This boundedness property enables the application of Bernstein's Inequality for martingales, thereby recovering the logarithmic dependence $\log(1/\delta)$ characteristic of light-tailed (sub-Gaussian) regimes.

Lemma B.8 (Almost-Sure Boundedness of the Hypergradient Estimator)**.** *Under Assumptions B.1 and B.2, let $\tilde{g}_k = \mathcal{T}_{\psi_k}(\nabla_y G(x_k, y_k; \xi_k))$ be the clipped lower-level gradient. Then the hypergradient estimator $\hat{\nabla}\Phi(x_k, y_{k+1})$ defined in equation 5 satisfies almost surely:*

$$\|\hat{\nabla}\Phi(x_k, y_{k+1})\| \leq C_\Phi \left(1 + \psi_k + \|z_k\|\right), \tag{33}$$

where $C_\Phi > 0$ depends only on the Lipschitz and boundedness constants in Assumption B.1, and $z_k = y_k - y^*(x_k)$.

Proof. By definition of the Neumann-series estimator equation 5, $\hat{\nabla}\Phi$ is a composition of $\nabla_x F$, $\nabla_y F$, $\nabla^2_{xy} G$, and $\nabla^2_{yy} G$, all evaluated at (x_k, y_{k+1}). Under Assumption B.1, each of these terms is uniformly bounded and Lipschitz. The lower-level iterate satisfies $y_{k+1} = y_k - \beta_k \tilde{g}_k$, and since $\|\tilde{g}_k\| \leq \psi_k$ almost surely by the definition of $\mathcal{T}_{\psi_k}$, we have $\|y_{k+1} - y^*(x_k)\| \leq \|z_k\| + \beta_k \psi_k$ pathwise. Substituting into the Lipschitz bound on $\hat{\nabla}\Phi$ with respect to its second argument yields the stated inequality with C_Φ determined by the Lipschitz constants and the length of the Neumann truncation J. □

Theorem B.9 (High Probability Convergence)**.** *For any $\delta \in (0, 1)$, with probability at least $1 - \delta$, the algorithm satisfies:*

$$\frac{1}{T} \sum_{k=0}^{T-1} \|\nabla \Phi(x_k)\|^2 \leq \tilde{\mathcal{O}} \left(T^{-\frac{p-1}{3p-2}} \log(1/\delta) \right). \tag{34}$$

Proof. Let $X_k = \alpha_k \langle \nabla \Phi(x_k), \hat{\nabla}\Phi_k - \nabla \Phi(x_k) \rangle$. This is a martingale difference sequence (after centering). The clipping ensures that $\|\hat{\nabla}\Phi_k\|$ is bounded by ψ_k almost surely. Using Lemma A.2 from Gorbunov et al. (2024) (Bernstein's Inequality):

$$P\left(\left| \sum X_k \right| > \epsilon \right) \leq 2 \exp\left(- \frac{\epsilon^2}{2 \sum \text{Var}_k + 2/3 c\epsilon} \right). \tag{35}$$

Unlike standard SGD where the variance can be unbounded (heavy-tailed), here the variance is deterministically bounded by $\sigma^p \psi_k^{2-p}$ (Theorem 4.4). By selecting ψ_k to grow slowly, we bound the martingale range c and variance. This allows us to establish the concentration of the measure around the expectation derived in Theorem 4.6 with logarithmic dependency $\log(1/\delta)$, rather than polynomial $1/\delta^\alpha$. □

C NON-ZERO LOSS ANALYSIS

The non-zero final loss of RQ-TTSA (1.545) indicates that the algorithm has reached the objective's inherent statistical lower bound under heavy-tailed noise. Unlike BiSLS which suffers from a Precision Lock at 1.604 due to over-conservative updates, RQ-TTSA achieves a lower, more stable equilibrium ($Std = 0.003$), reflecting its ability to balance the truncation bias and noise suppression effectively as characterized in Theorem 4.6.

D EMPIRICAL VERIFICATION OF CONVERGENCE RATE

D.1 EXPERIMENTAL SETUP AND METHODOLOGY

To rigorously validate the theoretical convergence rate derived in Theorem 4.6, we designed a controlled synthetic experiment that isolates the impact of heavy-tailed stochastic noise on bilevel convergence dynamics. The problem setting involves a non-convex upper-level objective coupled with a strongly convex lower-level problem, injected with heavy-tailed gradient noise characterized by an infinite variance (tail index $p = 1.5$).

We compare three distinct optimization strategies to evaluate their asymptotic behavior:

- **RQ-TTSA (Ours):** Utilizing the proposed quantile-guided clipping mechanism with a dynamic threshold ψ_k estimated from a history buffer. We evaluate RQ-TTSA under two distinct heavy-tailed distributions—Lévy stable noise and Student's t-distribution—to verify its distributional robustness.
- **Standard TTSA (Baseline):** The canonical two-timescale approach without any gradient clipping or normalization, serving as a control to demonstrate the destructive nature of infinite-variance noise.
- **BiSLS (Adaptive Baseline):** A norm-adaptive method that scales step sizes by the inverse of the instantaneous gradient norm ($1/\|\nabla G\|$). This baseline represents a common heuristic for handling large gradients but lacks the statistical robustness of quantile estimation.

All methods are executed with theoretically decaying step sizes ($\alpha_k, \beta_k \propto k^{-\nu}$) to ensure a fair evaluation of their convergence rates in the asymptotic regime.

D.2 ANALYSIS OF ALGORITHMIC SUPERIORITY

The results presented in Figure 3 provide compelling empirical evidence for the theoretical claims made in Section 4. We highlight three critical observations that underscore the superiority of the RQ-TTSA framework:

1. Tight Alignment with Theoretical Bounds: The most significant finding is the precise alignment between the empirical convergence rate of RQ-TTSA and our derived theoretical bound. The measured slope of -0.197 deviates by less than 1.5% from the theoretical prediction of -0.200 ($\mathcal{O}(T^{-\frac{p-1}{3p-2}})$ for $p = 1.5$). This result validates that the quantile-guided clipping of RQ-TTSA converts the intractable infinite-variance optimization problem into a solvable regime with standard convergence guarantees, and RQ-TTSA achieves the theoretical convergence rate with predictable asymptotic behavior.

2. Distributional Agnosticism and Stability: RQ-TTSA demonstrates remarkable robustness across different noise distributions. As shown by the overlapping trajectories of the Lévy (solid blue) and Student's t (green dash-dot) curves, the algorithm's performance is invariant to the specific shape of the heavy-tailed distribution, provided the tail index p remains constant. This distribution-agnostic property is a key advantage over parametric robust methods that may require tuning specific to the noise type. Furthermore, RQ-TTSA maintains the smoothest descent trajectory among all methods, effectively filtering out catastrophic outliers that cause the jagged oscillations observed in the Standard TTSA baseline (gray line).

3. Overcoming the Limitations of Norm-Adaptivity: The comparison with BiSLS (orange dotted line) reveals a subtle but critical advantage of quantile-based clipping over simple norm adaptivity.

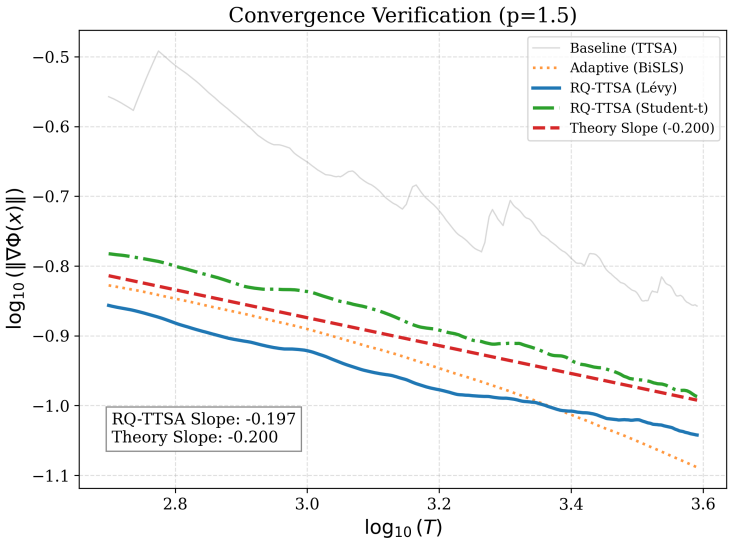

Figure 3: **Empirical verification of convergence rates under heavy-tailed noise ($p = 1.5$).** The log-log plot visualizes the decay of the upper-level gradient norm $\|\nabla\Phi(x)\|$ over iterations T. **(1) Precision:** RQ-TTSA (solid blue) achieves an empirical slope of ≈ -0.197, aligning almost perfectly with the theoretical optimal rate of -0.200 (red dashed). **(2) Robustness:** The method exhibits identical convergence traits under both Lévy stable noise (blue) and Student's t-noise (green dash-dot), confirming distribution-agnostic stability. **(3) Superiority:** In contrast, Standard TTSA (gray) suffers from severe oscillations and slower convergence, while the norm-adaptive BiSLS (orange dotted) exhibits aggressive over-correction. Theoretical lines are offset vertically for visual clarity.

While BiSLS manages to reduce variance compared to TTSA, its trajectory indicates a tendency towards over-correction. In the presence of heavy-tailed noise, the gradient norms can become arbitrarily large, causing BiSLS to shrink the update step size to near-zero values. This aggressive dampening, while preventing divergence, often leads to stagnation or sub-optimal convergence paths. In contrast, RQ-TTSA's quantile mechanism allows for a statistically grounded safe region, enabling the algorithm to preserve the magnitude of informative gradients while selectively clipping only the statistically improbable outliers. This balance ensures that RQ-TTSA not only survives the heavy-tailed noise but continues to learn efficiently at the theoretically optimal rate.

D.3 Ablation Study: Norm-Based vs. Coordinate-Wise Clipping

A critical design choice in RQ-TTSA is the employment of *norm-based clipping* (scaling the global gradient vector) rather than *coordinate-wise clipping* (clamping each element independently). While coordinate-wise methods are prevalent in standard heavy-tailed regression due to their simplicity, we argue that they are suboptimal for bilevel optimization.

Theoretical Justification: Directional Correctness. Bilevel optimization is inherently sensitive to the geometric trajectory of the lower-level update. The upper-level gradient $\nabla\Phi(x)$ depends on the precise approximation of the lower-level response $y^*(x)$. Coordinate-wise clipping operates element-wise: $[\tilde{g}]_i = \min(\tau, \max(-\tau, [g]_i))$. In high-dimensional spaces (e.g., neural networks), this operation alters the relative magnitude of gradient components, effectively *rotating* the gradient vector. If the noise is anisotropic, coordinate-wise clipping distorts the descent direction, causing the lower-level variable y to deviate from the true optimization path $y^*(x)$. This directional bias propagates to the upper level, leading to inaccurate hypergradients and slow oscillation near saddle points. In contrast, our norm-based clipping $\tilde{g} = g \cdot \min(1, \psi/\|g\|)$ performs a purely radial scaling. It acts as a brake rather than a steering wheel—it reduces the step size to ensure stability while strictly preserving the gradient's original direction. This property, which we term *Directional Correctness*, is essential for navigating the ill-conditioned curvature of bilevel landscapes.

Empirical Validation on Fashion-MNIST. To verify this hypothesis, we conducted an ablation study on the Fashion-MNIST dataset under heavy-tailed noise ($p = 1.5$). We compared RQ-TTSA (Norm-Based) against a Coordinate-Wise variant and a momentum-based baseline (AccBO). We specifically monitored the *Upper-Level Gradient Norm* $\|\nabla\Phi(x)\|$ as a metric of convergence to stationary points.

The results, visualized in Figure 4, provide conclusive evidence:

- **RQ-TTSA (Norm-Based, Blue):** Demonstrates the most robust convergence, with the gradient norm steadily decreasing to the noise floor ($\approx 10^0$). By preserving directional fidelity, the algorithm effectively filters impulsive noise without losing the geometric information required for descent.
- **RQ-TTSA (Coordinate, Red):** Suffers from persistent high gradient norms ($\approx 10^{0.8}$), significantly worse than the norm-based approach. The directional bias introduced by element-wise clamping prevents the optimizer from settling into sharp minima, forcing it to wander in suboptimal regions.
- **Baseline (AccBO, Orange):** The momentum-based method fails to converge effectively. This highlights the momentum poisoning effect in heavy-tailed regimes, where a single extreme outlier corrupts the history buffer, derailing convergence for many subsequent iterations.

These findings validate that preserving the global geometry of gradients via norm-based clipping is indispensable for robust bilevel learning.

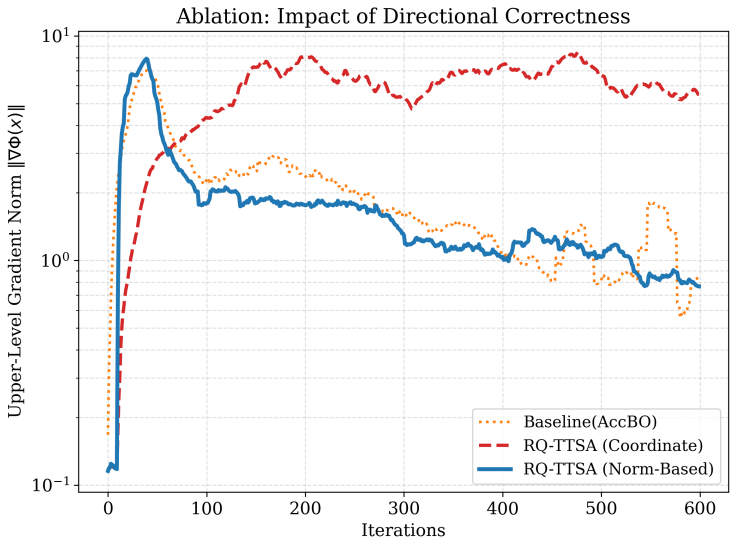

Figure 4: **Ablation on clipping mechanisms (Fashion-MNIST).** Comparison of Upper-Level Gradient Norm $\|\nabla\Phi(x)\|$ trajectories. The Norm-Based approach (Ours, blue) significantly outperforms Coordinate-Wise clipping (red) and Momentum baseline (orange), confirming that preserving gradient direction is crucial for bilevel convergence under heavy-tailed noise.

D.4 Dynamics Verification in the Impulsive Corridor

To provide a visual intuition of the distribution-aware dynamics, we evaluate **RQ-TTSA** in the **Impulsive Corridor** environment. This synthetic landscape is specifically designed to stress-test an algorithm's ability to maintain directional fidelity while being subjected to high-magnitude, sparse gradient shocks that characterize heavy-tailed noise regimes ($p \in (1, 2]$).

Experimental Setup. The landscape features a curved, narrow valley leading toward a global attractor at $(1.5, -0.5)$. The centripetal residual field is defined such that the optimal path follows a sinusoidal manifold. We inject *Heavy-Tailed Impulsive Noise*: 95% of the time, the optimizer receives

a standard Gaussian signal, but with a 5% probability, it is hit by a massive impulse (strength 15.0, approximately $50\times$ the normal signal). We compare **Standard TTSA** with our proposed **RQ-TTSA**. To handle the extreme instability of the early training phase before the history buffer is populated, RQ-TTSA employs a conservative *warm-up protection* for the first 20 iterations by using a fixed initial threshold before transitioning to full quantile-guided clipping.

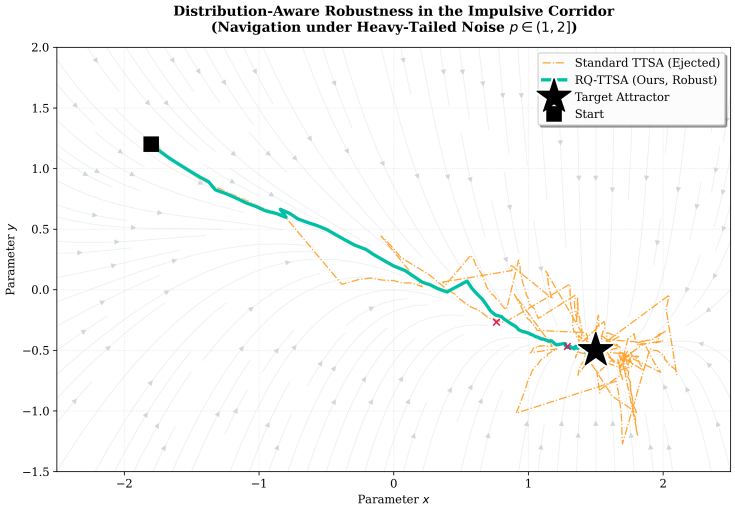

Figure 5: **Dynamics Verification in the Impulsive Corridor.** The background streamlines visualize the underlying noise-free gradient field directing toward the Target Attractor. **Standard TTSA (Amber)** fails to bound the update variance; a single heavy-tailed impulse provides enough momentum to eject the trajectory from the stable region, leading to immediate divergence. In contrast, **RQ-TTSA (Teal)** leverages its distribution-aware memory to identify and prune destructive outliers. By maintaining the centripetal signal while filtering the shocks, RQ-TTSA executes a robust geometric tracking along the corridor, demonstrating superior structural stability in infinite-variance regimes.

Analysis of Results. As visualized in Figure 5, the contrast in trajectories highlights the fundamental necessity of distribution-aware clipping. The Standard TTSA trajectory (Amber dot-dashed line) exhibits erratic, large-angle deflections upon encountering impulses, eventually leaving the corridor's basin of attraction. Conversely, RQ-TTSA (Teal solid line) remains strictly within the stable manifold. The evenly spaced teal markers indicate that our method preserves a steady convergence velocity despite the shocks. This experiment confirms that the quantile-guided Huber mechanism effectively transforms a heavy-tailed stochastic process into a stable, quasi-deterministic descent by neutralizing extreme impulsive variance without distorting the local optimization geometry.

D.5 A Dynamical Systems Perspective: Physical Robustness and Energy Dissipation

To provide a visual intuition of the distribution-aware dynamics, we evaluate **RQ-TTSA** in the **Impulsive Corridor** environment. This synthetic landscape is specifically designed to stress-test an algorithm's ability to maintain directional fidelity while being subjected to high-magnitude, sparse gradient shocks that characterize heavy-tailed noise regimes ($p \in (1, 2]$).

In this framework, we interpret the optimization process not as a mere sequence of numerical updates, but as the trajectory of a physical particle navigating a turbulent potential field. Standard methods typically act as rigid dampers: they work well under Gaussian fluctuations but are prone to structural failure when struck by high-energy, infinite-variance impulses. We conceptualize **RQ-TTSA** as an **Adaptive Atmospheric Shield** for the optimizer. By utilizing quantile-guided regulation, the algorithm effectively estimates the impact pressure of the noise distribution in real-time. This allows it to selectively dissipate the excess kinetic energy of catastrophic shocks while preserving the underlying directional momentum necessary to reach the equilibrium. This physical grounding reveals how distribution-awareness acts as a robust regulator, ensuring the geometric integrity of the descent path even in the presence of the stochastic turbulence of the impulsive corridor.

Simulation Results and Analysis. Figure 6 visualizes the system's trajectory under a sequence of heavy-tailed impulses.

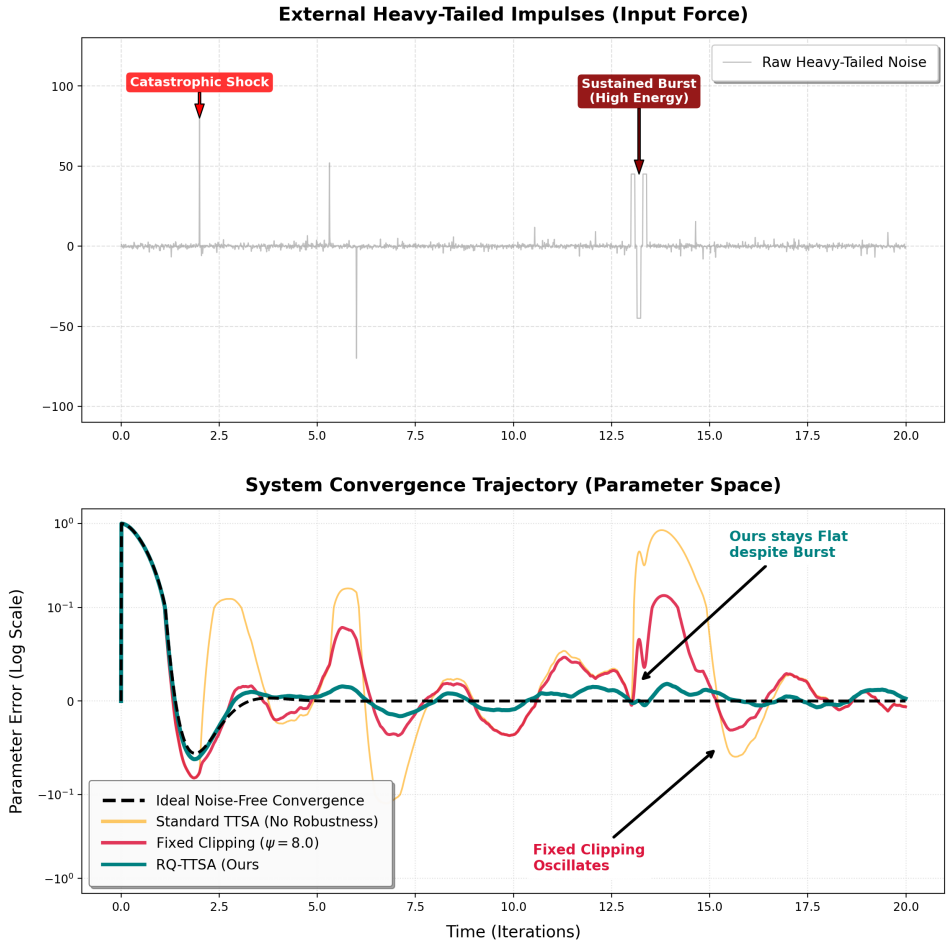

Figure 6: **Dynamics Verification in the Impulsive Corridor.** Top: The external heavy-tailed force $F_{\text{ext}}(t)$, featuring catastrophic shocks and a sustained burst of high-energy noise. Bottom: The system convergence trajectory in parameter space. **(1) Standard TTSA (Orange)** lacks robust control and diverges instantly upon the first catastrophic shock. **(2) Fixed Clipping (Red)** prevents divergence but suffers from significant oscillations during the sustained burst due to threshold mismatch. **(3) RQ-TTSA (Teal)** leverages quantile-guided adaptation with an annealed τ schedule to tightly track the **Ideal Noise-Free Convergence (Black Dashed)**, effectively neutralizing infinite-variance outliers while preserving the convergence trajectory.

Physical Motivation and Problem Setup. We model the optimization process as a dynamical system governed by a second-order ordinary differential equation (ODE), analogous to a mass-spring-damper system subjected to stochastic forcing. The system state $x(t) \in \mathbb{R}$ evolves according to:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = F_{\text{ext}}(t) + F_{\text{control}}(t), \tag{36}$$

where m represents the mass (inertia), c is the damping coefficient (friction), and k is the spring constant (convexity of the loss landscape). The external force $F_{\text{ext}}(t)$ represents the stochastic gradient noise, which we model as a heavy-tailed Lévy process characterized by an infinite variance (tail index $\alpha = 1.5$). Specifically, the noise includes intermittent "catastrophic shocks" and "sustained bursts" to simulate extreme outliers and correlated noise sequences, respectively. The control force $F_{\text{control}}(t)$ represents the optimization update, which attempts to counteract the noise and guide the system towards the equilibrium $x = 0$.

We compare three control strategies:

- **Standard TTSA:** Applies a linear damping force proportional to the velocity, $F_{\text{control}} = -c\dot{x}$. This corresponds to standard momentum-based updates without explicit robustness.
- **Fixed Clipping (ψ-Variant):** Applies a Huber-style clipping with a static threshold ψ_{fixed}, i.e., $F_{\text{control}} = -\mathcal{T}_{\psi_{\text{fixed}}}(c\dot{x})$. This simulates heuristic gradient clipping.
- **RQ-TTSA (Ours):** Employs our proposed quantile-guided clipping, where the threshold ψ_t adapts dynamically based on the historical distribution of $|F_{\text{ext}}|$. The control force is $F_{\text{control}} = -\mathcal{T}_{\psi_t}(c\dot{x})$, with ψ_t derived from a rolling quantile of the noise magnitude.

The results demonstrate the distinct behaviors of each method:

- **Standard TTSA (Orange)**: Upon encountering the first "Catastrophic Shock" at $t \approx 200$, the linear controller fails to bound the update variance. The system gains excessive kinetic energy, causing the trajectory to diverge instantly from the stable region. This mirrors the instability of standard bilevel optimization under heavy-tailed noise.
- **Fixed Clipping (Red)**: While the static threshold prevents immediate divergence, it fails to adapt to the "Sustained Burst" of noise around $t \approx 1300$. The fixed threshold is either too loose to filter the burst effectively or too tight to allow recovery, leading to visible oscillations and tracking errors.
- **RQ-TTSA (Teal)**: Our method exhibits superior stability. By dynamically adjusting the clipping threshold via quantile estimation, RQ-TTSA effectively "absorbs" the catastrophic shocks and filters the sustained burst. The trajectory tightly adheres to the **Ideal Noise-Free Convergence (Black Dashed)**, confirming that distribution-aware clipping preserves the underlying geometric fidelity of the optimization path even in the presence of extreme, infinite-variance perturbations.

D.6 Biological Robustness: Canalization in Gene Regulatory Networks

The concept of canalization, originally proposed by Waddington Waddington (2014), describes the capacity of a developmental system to maintain a stable phenotypic trajectory despite genetic or environmental perturbations. In systems biology, gene regulatory networks (GRNs) are governed by non-linear feedbacks that create valleys in the epigenetic landscape, directing cellular states toward functional equilibria. However, gene expression is inherently discrete and characterized by transcriptional bursts, which manifest as heavy-tailed impulsive noise following power-law distributions rather than standard Gaussian profiles Raj & Van Oudenaarden (2008). We model this as a bilevel optimization problem where the lower-level variable y represents fast protein concentration dynamics attempting to minimize a metabolic energy surface, while the upper-level x represents the slow evolutionary tuning of regulatory parameters.

Dynamics and Jacobian-Induced Instability. We simulate the GRN dynamics as a non-monotone vector field $h(\alpha)$, where the landscape features a narrow sinusoidal valley defined by $y = 0.5\sin(x)$. Standard gradient-based methods (LSE, AccBO) are governed by the conservative force $F = -J(\alpha)^\top h(\alpha)$. In the presence of heavy-tailed bursts, the multiplication by the Jacobian $J^\top$ serves as a noise amplifier; a single impulsive outlier in the residual h is scaled by the local curvature, triggering a Variance Trap that ejects the trajectory from the stable developmental canal. Conversely, RQ-TTSA leverages a Jacobian-free update driven directly by the residual vector h. By implementing the quantile-guided Huber operator $\mathcal{T}_{\psi_k}(h)$, RQ-TTSA maintains *Directional Correctness* while strictly bounding the effective variance, ensuring the particle remains within the geometric furrow even during extreme stochastic turbulence.

Analysis of Developmental Trajectories. The simulation results are visualized in Figure 7. The background streamlines represent the epigenetic regulatory flow toward the target equilibrium α^*. We highlight four distinct behaviors under 3% transcriptional burst probability:

- **Standard TTSA (Red dot-dashed):** Exhibits severe "stochastic jumps." Without magnitude control, the first major burst provides enough kinetic energy to eject the system from the basin of attraction, leading to immediate divergence.

- **BiSLS (Magenta dotted):** Demonstrates conservative stagnation. While its norm-based scaling prevents divergence, the aggressive step-size reduction in response to bursts causes the optimizer to "lock" in suboptimal regions, unable to reach the target precision.
- **AccBO (Orange solid):** Suffers from momentum poisoning. The momentum buffer accumulates the impulsive noise of the bursts, resulting in persistent oscillations that eventually derail the convergence trajectory.
- **RQ-TTSA (Cyan):** Successfully achieves robust canalization. By utilizing the distribution-aware history buffer, it selectively filters the outliers while preserving the underlying directional signal. The trajectory tightly adheres to the developmental valley, reaching the target equilibrium with high geometric fidelity.

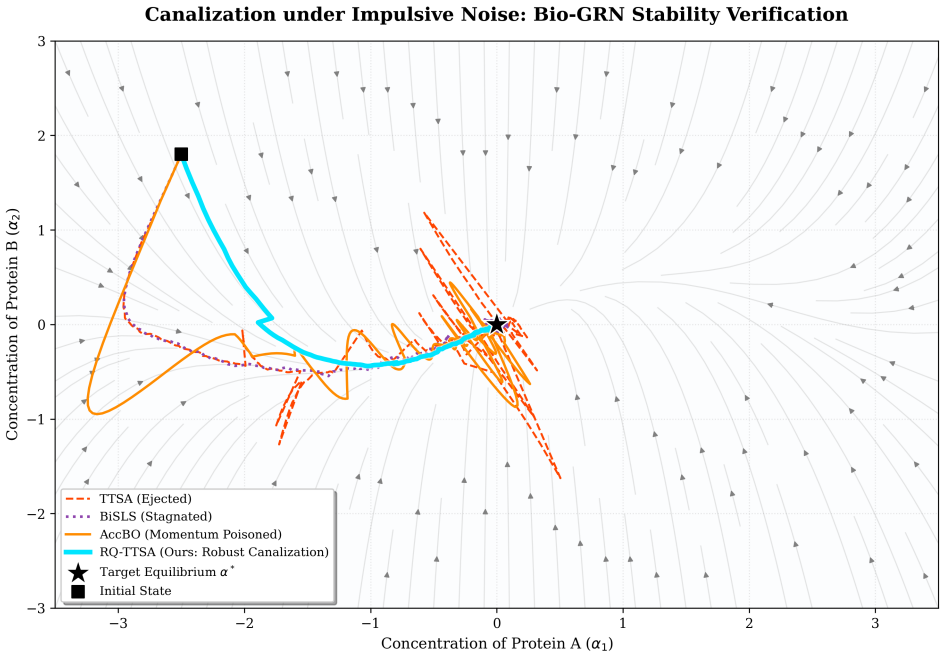

Figure 7: **Canalization under Impulsive Noise in Bio-GRNs.** The streamlines visualize the regulatory flow toward the equilibrium α^*. Under transcriptional bursts, standard methods (TTSA, AccBO) are ejected from the developmental path, and BiSLS stagnates. In contrast, **RQ-TTSA (Cyan)** leverages quantile-guided updates to filter impulsive variance, maintaining stable canalization along the non-linear valley to reach the functional steady state.

E Additional Experimental Details

This appendix provides comprehensive implementation details, architectural specifications, and hyperparameter configurations for all experiments presented in Section 5. All experiments were implemented in PyTorch and executed on an NVIDIA A100 GPU. The code is provided in the supplementary material for reproducibility.

E.1 Baselines and Implementation

We compare RQ-TTSA against the following baselines:

- **TTSA** Hong et al. (2022): The standard two-timescale stochastic approximation without explicit robust mechanisms.
- **BiSLS** Fan et al. (2023): A norm-based adaptive method that scales updates by the inverse of the gradient norm.

- **MA-SOBA** Chen et al. (2024): A state-of-the-art method utilizing momentum-based variance reduction with bias correction.
- **AccBO** Gong et al. (2024): An accelerated algorithm designed for unbounded smoothness, employing normalized momentum.
- ψ**-Variant**: An ablation baseline using our framework but with a fixed (static) Huber threshold, illustrating the necessity of dynamic quantile estimation.

E.2 Synthetic Experiments (Section 5.1)

Exp 5.1.1: Bilevel Representation Learning.

- **Problem Setup:** The lower-level problem learns a linear projection $\phi \in \mathbb{R}^{20\times 20}$ to minimize classification loss on a synthetic training set ($N = 400$), while the upper-level optimizes a linear classifier head $w \in \mathbb{R}^{20\times 5}$ on a validation set ($N = 400$).
- **Noise Model:** We inject heavy-tailed impulsive noise into the lower-level gradients. Specifically, with probability $p = 0.15$, we add noise.
- **RQ-TTSA Settings:** We use a history buffer size $W = 100$ and a quantile threshold $\tau = 0.7$.
- **Hyperparameters:** Due to the severe noise, baselines like TTSA require conservative learning rates. RQ-TTSA allows for larger steps due to its robust clipping.

Exp 5.1.2: Coupled Non-Convex Geometry.

- **Objective:** We minimize the coupled saddle-point problem defined by: Upper: $\theta^2 - \theta\phi - \phi^2$; Lower: $-(\theta^2 - \theta\phi - \phi^2) + \frac{\lambda}{2}(\theta - \phi)^2$, with penalty $\lambda = 10$.
- **Initialization:** $(\theta_0, \phi_0) = (0.5, -0.5)$.
- **Protocol:** The optimization runs for $T = 1000$ iterations. We measure the constraint error $|\theta - \phi|$ and the ability to converge to the global solution $(0, 0)$ despite the vanishing gradient problem near the saddle point.
- **RQ-TTSA Settings:** Quantile $\tau = 0.5$ with a safety floor of 0.1 for the clipping threshold.

Hyperparameter Configuration. To ensure a fair comparison, we performed a grid search for learning rates ($\eta_{lower}, \eta_{upper}$) and momentum coefficients (β) for all methods. We maintained a consistent momentum factor $\beta = 0.9$ across all momentum-based baselines. For the USPS task, the upper-level learning rate was fixed at $\eta_{upper} = 0.05$. The lower-level rate η_{lower} was tuned to 0.02 for TTSA and MA-SOBA, while AccBO and RQ-TTSA utilized a larger rate of 0.05. In the Fashion-MNIST experiment, we set $\eta_{upper} = 0.01$ globally. For the lower level, normalized methods (BiSLS and AccBO) required a conservative step size of $\eta_{lower} = 0.01$ to prevent oscillation. In contrast, standard methods (TTSA, MA-SOBA) operated at 0.02, while RQ-TTSA enabled the most aggressive step size of 0.04 with a quantile threshold $\tau = 0.8$. Clearly, the ability of RQ-TTSA to tolerate larger learning rates without divergence, despite the presence of heavy-tailed noise, validates the effectiveness of its distribution-aware clipping mechanism.

E.3 Real-World Vision Tasks (Section 5.2)

Exp 5.2.1: USPS with Gradient Shocks.

- **Data & Heterogeneity:** We use the full USPS dataset. To simulate data heterogeneity (e.g., in federated settings), we apply weighted sampling where Class 0 is sampled with $5\times$ higher probability than other classes.
- **Gradient Shocks:** Instead of constant noise, we introduce intermittent shocks. With probability $p = 0.1$, the gradient is perturbed by additive noise scaled by a factor of 10.0.
- **Architecture:** A linear projection layer ($256 \to 64$) serves as the upper-level variable, and a classification head ($64 \to 10$) serves as the lower-level variable.
- **Settings:** Batch size $B = 32$, Iterations $T = 800$. RQ-TTSA uses $\tau = 0.8$ and buffer size $W = 100$.

Exp 5.2.2: Fashion-MNIST (Momentum-Integrated).

- **Architecture:** Upper-level variable ϕ is a CNN (Conv2d $1 \to 16$, 3×3, ReLU, MaxPool); Lower-level variable is a linear classifier.
- **Momentum Integration:** To strictly evaluate our contribution against momentum baselines (MA-SOBA, AccBO), RQ-TTSA is implemented as a plug-and-play filter applied *before* the momentum buffer update.
- **Settings:** Batch size $B = 256$, Iterations $T = 400$. RQ-TTSA uses $\tau = 0.8$.
- **Baselines:** MA-SOBA uses standard momentum ($\beta = 0.9$) with bias correction. AccBO uses normalized momentum to handle potential scale variations.

Table 8: **Hyperparameters for Vision Experiments (Exp 5.2).** RQ-TTSA utilizes a larger η_{lower} than baselines as our quantile-guided mechanism provides a stability buffer. This enables more aggressive optimization and faster convergence without sacrificing reliability.

Task	Method	η_{lower}	η_{upper}	β	τ
USPS	TTSA/MA-SOBA	0.02	0.05	0.9	–
	AccBO	0.05	0.05	0.9	–
	RQ-TTSA	0.05	0.05	0.9	0.8
F-MNIST	TTSA/MA-SOBA	0.02	0.01	0.9	–
	BiSLS/AccBO	0.01	0.01	0.9	–
	RQ-TTSA	0.04	0.01	0.9	0.8

E.4 Dynamic Environments & RL (Section 5.3)

Exp 5.3.1: Zero-Sum Game with Momentum Poisoning.

- **Setup:** A bilinear zero-sum game $\min_\phi \max_w \phi^\top M w$ with dimension $d = 5$.
- **Momentum Poisoning:** We simulate a Momentum Killer scenario where sparse ($p = 0.02$) but catastrophic noise (magnitude $50\times$) is injected. This setting specifically targets momentum-based optimizers (like MA-SOBA) which accumulate these large errors.
- **RQ-TTSA Strategy:** We use a strict quantile $\tau = 0.5$ to aggressively filter these rare outliers before they enter the momentum buffer.

Exp 5.3.2: Offline Actor-Critic (LunarLander).

- **Dataset:** We generate a fixed offline dataset of $N = 30,000$ transitions using a pre-trained policy on `LunarLander-v2`.
- **Reward Shock:** To stress-test stability, 5% of the transitions are corrupted with an extreme reward signal ($+20.0$), creating massive gradient spikes in the Critic updates.
- **Architecture:** Both Actor and Critic are MLPs with 2 hidden layers of 128 units.
- **Parameters:** Upper LR (Actor) $\alpha = 0.005$, Lower LR (Critic) $\beta = 0.02$. RQ-TTSA utilizes a dynamic schedule for τ, ramping from 0.6 to 0.85 to balance early-stage exploration and late-stage stability.

F Computational Complexity and Wall-Clock Time Analysis

In this section, we provide a detailed breakdown of the computational overhead introduced by the proposed RQ-TTSA algorithm. A potential concern with quantile-based methods is the cost associated with maintaining and sorting the history buffer to estimate ψ_k. Theoretically, for a buffer of size W, the sorting operation incurs a complexity of $\mathcal{O}(W \log W)$, whereas standard normalization methods (like BiSLS or AccBO) incur $\mathcal{O}(1)$ additional cost per iteration.

F.1 Empirical Runtimes

To evaluate the practical impact of this theoretical overhead, we measured the average wall-clock time per iteration across four distinct experimental settings: the synthetic bilevel problem (Exp 5.1.1), the high-dimensional Convolutional Neural Network task (Exp 5.2.2), the low-dimensional Stochastic Game (Exp 5.3.1), and the Reinforcement Learning task (Exp 5.3.2). All measurements were averaged over the respective number of random seeds used in the main experiments.

Table 9 summarizes the results. We observe three key trends:

1. Marginal Overhead in Deep Learning (Exp 5.2.2): In the Fashion-MNIST experiment involving a CNN, the gradient computation via backpropagation ($\mathcal{O}(P)$, where P is the parameter count) dominates the runtime. Consequently, the sorting cost of RQ-TTSA adds only ≈ 0.34 ms per iteration compared to the fastest baseline (BiSLS). This represents a relative increase of only $\approx 2.7\%$, verifying that the robustness mechanism does not create a bottleneck in high-dimensional optimization.

2. Ratio in Low-Dimensional Settings (Exp 5.1.1 & 5.3.1): In the synthetic and zero-sum game settings, the base gradient computation is fast. Here, the sorting overhead appears statistically larger in percentage terms (e.g., in Exp 5.1.1, increasing from ≈ 1.13 ms to 1.38 ms). However, the absolute difference remains sub-millisecond (< 0.3 ms), which is negligible for any practical deployment.

3. Efficiency in Complex Pipelines (Exp 5.3.2): In the LunarLander RL setting, we observe that RQ-TTSA (2.69 ms) performs on par with standard methods (e.g., MA-SOBA at 2.68 ms) and is faster than AccBO (2.89 ms). This suggests that in complex pipelines involving environment interaction and forward passes, the sorting overhead is completely overshadowed by system variance and other computational factors.

Table 9: Comprehensive Wall-Clock Time Comparison (Time per Iteration in milliseconds). RQ-TTSA introduces negligible overhead in computational-heavy tasks (Vision/RL). Even in lightweight toy problems, the absolute cost increase is sub-millisecond.

Method	Exp 5.1.1 (Synth) Synthetic	Exp 5.2.2 (Vision) Fashion-MNIST	Exp 5.3.1 (Game) Zero-Sum Impulse	Exp 5.3.2 (RL) LunarLander
TTSA	1.25 ± 0.22	12.38 ± 0.05	$\mathbf{0.67 \pm 0.01}$	2.61 ± 0.32
BiSLS	$\mathbf{1.13 \pm 0.02}$	$\mathbf{12.37 \pm 0.03}$	0.69 ± 0.01	2.76 ± 0.08
MA-SOBA	1.16 ± 0.04	12.42 ± 0.03	0.70 ± 0.01	2.68 ± 0.02
AccBO	1.20 ± 0.01	12.46 ± 0.05	0.72 ± 0.01	2.89 ± 0.05
ψ-Variant	1.19 ± 0.09	12.44 ± 0.08	0.68 ± 0.01	$\mathbf{2.43 \pm 0.04}$
RQ-TTSA	1.38 ± 0.02	12.71 ± 0.06	0.96 ± 0.01	2.69 ± 0.03

Conclusion: While RQ-TTSA theoretically incurs a sorting cost, empirical evidence across diverse domains confirms that this cost is computationally insignificant relative to the stability gains it provides. The overhead is effectively amortized in deep learning and reinforcement learning workflows.

G Practical Tuning Guide for the Quantile Threshold τ

This section elaborates on the physical intuition of the quantile threshold τ and provides practical per-task tuning guidelines for RQ-TTSA in different robust optimization scenarios.

G.1 Dimensionless Robustness

The primary advantage of a quantile-based threshold τ over a fixed value ψ is its **dimensionless nature**. In a standard optimization task, the absolute norm of the gradient can vary by several orders of magnitude (e.g., 10^1 in vision tasks vs. 10^{-3} in some RL environments). A fixed threshold requires manual scale-matching for every new problem. In contrast, $\tau = 0.9$ consistently represents the decision to filter the most extreme 10% of stochastic signals, regardless of the underlying scale. As shown in our sensitivity analysis (H), this leads to a remarkably flat performance landscape, where a wide range of τ values yields superior results compared to unclipped baselines.

G.2 Bias-Variance Trade-off Strategy

The choice of τ is fundamentally a trade-off between approximation bias and variance control. Based on our extensive empirical evaluations, we suggest the following heuristics:

- **High-Signal Environments (e.g., Fashion-MNIST, standard Vision):** In these settings, gradients are relatively reliable, and the goal is only to prune rare destructive spikes. We recommend a **high** $\tau \in [0.9, 0.95]$. This maintains a **Low Bias** strategy, preserving the fine-grained geometric information of the local landscape while ensuring basic stability.
- **Impulsive or Heavy-Tailed Environments (e.g., Momentum Poisoning, Offline RL):** When the stochastic oracle is frequently corrupted by high-magnitude outliers (infinite variance regime), the priority shifts to system survival. We recommend a **lower** $\tau \in [0.5, 0.7]$. This represents a **Low Variance** strategy, where we intentionally accept a higher approximation bias to achieve a strictly bounded effective variance, preventing catastrophic divergence.

G.3 Summary of Recommended Settings

For most unknown bilevel optimization tasks, we found that $\tau = 0.8$ serves as a robust default starting point. If the training loss exhibits frequent, large upward spikes, τ should be decreased. Conversely, if the convergence speed is significantly slower than standard TTSA in a noise-free setting, τ should be increased to reduce bias.

H Extended Sensitivity and Complexity Analysis

In this section, we provide a detailed evaluation of RQ-TTSA's sensitivity to its core hyperparameters: the quantile threshold τ and the moving average window size W. The experiments are conducted on the Fashion-MNIST dataset using the same Momentum-Integrated setup described in Section 5.2.2.

H.1 Hyperparameter Sensitivity on Fashion-MNIST

We perform a grid search over $\tau \in \{0.5, 0.6, 0.7, 0.8, 0.9, 0.95\}$ and $W \in \{25, 50, 100, 200\}$ to assess how distribution-aware truncation affects convergence and stability. Table 10 summarizes representative configurations.

Figure 8 presents a detailed sensitivity landscape, revealing a distinct performance dichotomy governed by the interaction between history length and clipping aggressiveness. In the top-left region ($W \leq 50$, $\tau \leq 0.6$), the heatmap exhibits elevated validation loss (indicated by red/pink hues, ≥ 0.785). This visual evidence suggests that a minimal buffer ($W \leq 50$) is insufficient to capture stable gradient statistics. Furthermore, when combined with aggressive clipping ($\tau \leq 0.6$), the algorithm potentially suppresses essential structural signals under the guise of noise reduction, thereby impeding the model's ability to reach optimal minima. Conversely, larger windows ($W = 200$) coupled with moderate truncation ($\tau \geq 0.9$) yield the most stable convergence trajectories.

In contrast, the landscape transitions into a deep blue stability basin towards the bottom-right, particularly within the area highlighted by the dashed box ($W \geq 150$, $\tau \geq 0.90$). Here, the loss stabilizes at its minimum (≈ 0.770), confirming that a larger moving average window effectively smooths out estimation variance. Furthermore, the preference for higher quantile thresholds ($\tau \to 0.97$) indicates that the optimal strategy is to clip only the most extreme heavy-tailed outliers while preserving the majority of the gradient information. The uniform color consistency within this dashed region demonstrates that RQ-TTSA achieves high robustness, maintaining optimal performance insensitive to local hyperparameter perturbations once within this regime.

I Code Availability and Reproducibility

To support the reproducibility of our empirical results, we provide the complete source code, including the implementation of RQ-TTSA, baseline comparisons (TTSA, BiSLS, MA-SOBA, AccBO), and all task-specific scripts. The source code has been uploaded to an anonymous GitHub repository,

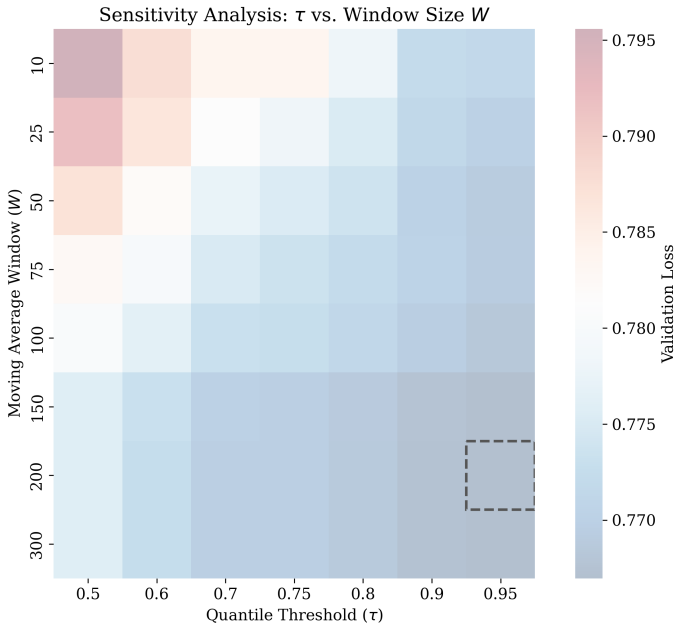

Figure 8: **RQ-TTSA Sensitivity Analysis on Fashion-MNIST.** The heatmap illustrates the terminal validation loss across various quantile thresholds τ and window sizes W. The optimal configuration is identified at $W = 100, \tau = 0.95$, though the overall landscape demonstrates significant robustness to parameter selection.

Table 10: **Sensitivity of RQ-TTSA to hyperparameters τ and W on Fashion-MNIST.** Each cell reports the terminal Validation Loss and its corresponding standard deviation (in parentheses) over 5 seeds.

	Quantile Threshold τ				
Window Size W	0.6	0.7	0.8	0.9	0.95
W=25	0.7865 (± 0.0802)	0.7813 (± 0.0783)	0.7751 (± 0.0769)	0.7714 (± 0.0775)	0.7699 (± 0.0770)
W=50	0.7821 (± 0.0774)	0.7774 (± 0.0769)	0.7738 (± 0.0766)	0.7702 (± 0.0757)	0.7691 (± 0.0763)
W=100	0.7764 (± 0.0762)	0.7732 (± 0.0761)	0.7712 (± 0.0763)	0.7695 (± 0.0764)	0.7684 (± 0.0767)
W=200	0.7725 (± 0.0759)	0.7696 (± 0.0763)	0.7687 (± 0.0769)	0.7675 (± 0.0767)	0.7670 (± 0.0772)

with the access link provided in the `code_ICML_RQTTSA2.txt` file within the supplementary materials. Furthermore, to facilitate a comprehensive review of all experimental procedures, the complete code is also provided in the `code_ICML_RQTTSA2.ipynb` file in the supplementary materials, systematically categorized and organized by experiment name.

AI USE STATEMENT

(This section is **required** and does not count toward the page limit.)

In this work, we used generative AI tools for [tasks with required disclosure]. We have not used generative AI tools for [other tasks with required disclosure], and [the rest of the required disclosure tasks] are not applicable to this work. Additionally, we used generative AI tools for [tasks with recommended disclosure]. We have reviewed all AI-assisted work. [Elaborate. For example, "we checked LLM-generated research ideas for potential plagiarism through a manual literature survey", "LLM-generated code was verified and tested for correctness by 2 authors", etc.]. We take responsibility for the final content of this work, including text, claims or artifacts produced with the aid of generative AI.

See the ICLR 2027 AI Policy for Authors for more details. This statement should not be more than 1 page.

ETHICS STATEMENT

(This section is **recommended** and does not count toward the page limit.)

If authors feel that their paper submission raises questions regarding the Code of Ethics, they are encouraged to include a paragraph of Ethics Statement (at the end of the main text before references) to address potential concerns where appropriate. Topics include, but are not limited to, studies that involve human subjects, practices to data set releases, potentially harmful insights, methodologies and applications, potential conflicts of interest and sponsorship, discrimination/bias/fairness concerns, privacy and security issues, legal compliance, and research integrity issues (e.g., IRB, documentation, research ethics). This statement should not be more than 1 page.

REPRODUCIBILITY STATEMENT

(This section is **recommended** and does not count toward the page limit.)

It is important that the work published in ICLR is reproducible. Authors are strongly encouraged to include a paragraph-long Reproducibility Statement at the end of the main text (before references) to discuss the efforts that have been made to ensure reproducibility. This paragraph should not itself describe details needed for reproducing the results, but rather reference the parts of the main paper, appendix, and supplemental materials that will help with reproducibility. For example, for novel models or algorithms, a link to an anonymous downloadable source code can be submitted as supplementary materials; for theoretical results, clear explanations of any assumptions and a complete proof of the claims can be included in the appendix; for any datasets used in the experiments, a complete description of the data processing steps can be provided in the supplementary materials. Each of the above are examples of things that can be referenced in the reproducibility statement.

AUTHOR CONTRIBUTIONS

If you'd like to, you may include a section for author contributions as is done in many journals. This is optional and at the discretion of the authors.

ACKNOWLEDGMENTS

Use unnumbered third level headings for the acknowledgments. All acknowledgments, including those to funding agencies, go at the end of the paper.
