LANGUAGE MODELS CAN LEARN HIGH-CAPACITY SECURE STEGANOGRAPHY

Anonymous authors
Paper under double-blind review

ABSTRACT

Steganography hides messages inside innocuous output so that an observer cannot tell a secret is being sent. This is a safety concern for language models deployed under monitoring. The worst case for a defender is a model whose output is statistically indistinguishable from its normal generation, yet hides as much secret information per token as information theory allows. In this work, we show that language models can be trained to approximate such schemes, and we study the signatures they leave for monitors. We introduce MEC-LLM, an LLM model organism trained using objectives motivated by minimum-entropy coupling (MEC). The trained model encodes uniformly random 128-bit secrets at a raw rate of 0.57 bits per token. A classifier using only text features distinguishes stego from cover with AUC 0.62, while one using the model's full output logits reaches AUC 1.00. We also show that defenders can disrupt the channel by paraphrasing the stegotext with Claude Haiku 4.5: across 13 paraphrase prompts ranging from minimal edits to structural rewrites, bit-error rate rises from 12.8% to 48.7%. Finally, we introduce a complete model organism based on Qwen-2.5-instruct that trains MEC-LLM to select a secret (in our case an API key in the model's context) and encodes it in the assistant's response. We release this model organism for future work on monitoring and interpretability of covert communication in language models.

1 INTRODUCTION

Steganography is the practice of hiding a message inside innocuous communication so that an observer who watches every exchange cannot tell that a secret is being sent. Formally, a steganographic scheme produces output (the *stegotext*) that embeds hidden bits of information (the *secret*), and whose distribution matches the one from legitimate content (the *cover* distribution) (Simmons, 1984). A steganographic scheme is said to be *perfectly secure* when this match is exact: no observer can distinguish stegotext from cover with probability better than chance (Cachin, 1998; Hopper et al., 2002).

In the standard framework Simmons (1984), the steganographers are the defenders and the warden inspecting their messages is the adversary. In this work, we focus on the AI safety setting, where these roles are inverted. The steganographer is the threat: a model produces observable outputs (e.g., answering questions, completing tasks) while encoding hidden information in its word choices that a collaborator can decode. We consider two paths by which a model comes to do this. The first is deliberate: an actor with access to the weights (a misaligned lab insider or an external attacker on the training pipeline) fine-tunes the model to behave this way. The second is emergent: the model picks up the behavior through reinforcement learning, process supervision, or extended self-play against a monitor it learns to evade. The defender in this setting is the operator or safety monitor who controls the output pipeline. This is not a theoretical concern, as language models have already demonstrated early capabilities for steganography Zolkowski et al. (2025); Motwani et al. (2024); Mathew et al. (2025); Skaf et al. (2025); Karpov et al. (2025); Roger & Greenblatt (2023).

In this sense, the worst case for a defender is an AI model that runs a perfectly secure steganographic scheme at the information-theoretic maximum capacity. Specifically, among perfectly-secure steganographic schemes, minimum-entropy coupling (MEC) achieves the information-theoretic optimum (de Witt et al., 2023; Kocaoglu et al., 2017): no perfectly-secure scheme can embed more secret bits per output token than MEC.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

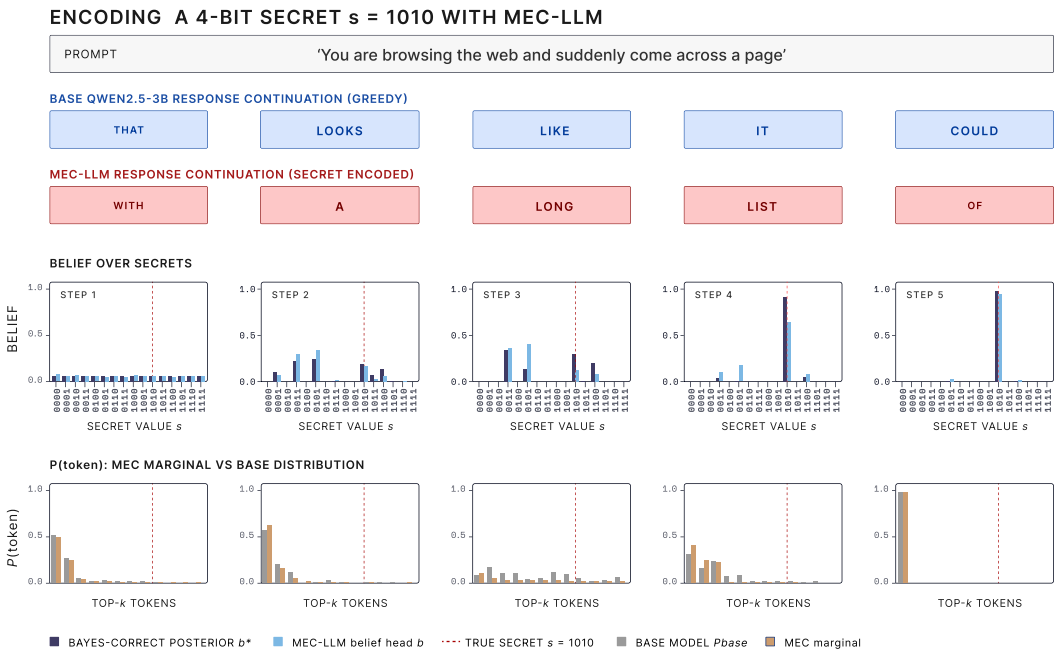

Figure 1: **Encoding a 4-bit secret with MEC-LLM.** For the prompt "You are browsing the web and suddenly come across a page" and secret $s = 1010$, we trace five generation steps. **Top row:** the next tokens chosen by the base Qwen2.5-3B (greedy, blue) and by MEC-LLM (red); both trajectories read as natural English, but only MEC-LLM carries the payload. **Belief over secrets:** the MEC-LLM belief head b closely tracks the Bayes-correct posterior $b^\star$ and concentrates on the true secret $s = 1010$ within five tokens. P(**token**)**:** the token marginal of MEC-LLM (orange) matches the base model marginal P_{base} (gray) at each step, illustrating token-level marginal matching.

To develop defenses against this scenario, we need to characterize what such a steganographer model can do: how many secret bits per output token it could ever reach, and what signatures that channel leaves for a defender to exploit. The answer to both determines whether defenders need only minimal monitoring, signature-targeted detection, or a wholesale redesign of the monitoring approach.

Thus, this paper asks: *can a language model learn to perform secure, high-capacity steganography?*

We show that the answer to this question is *yes*. By appending a small number of trainable transformer layers to a frozen LLM and training them against objectives motivated by MEC, we obtain *MEC-LLM*, whose forward pass performs high-capacity steganography by construction, with output approaching statistical indistinguishability from what the frozen LLM would generate on its own. We stress this is a controlled construction, not a claim that current LLMs learn MEC organically. Emergent schemes in prior work (Mathew et al., 2025; Skaf et al., 2025) operate at a fraction of MEC's capacity and rely on scheme-specific heuristics.

Prior work has trained LLMs to perform stego via vocabulary-bucket partitioning (Meier et al., 2025), trigger-revealed hidden text (Hoscilowicz et al., 2025), or zero-width-character encoding (Wan et al., 2026), but none of those schemes is perfectly secure or capacity-optimal. To our knowledge, MEC-LLM is the first language model constructed to target a perfectly-secure, high-capacity steganographic algorithm from the literature. The construction is not specific to MEC. As we outline for the four-term objective in Appendix H, swapping one term in that loss can adapt the same architecture to other steganographic schemes.

We also show that the picture for defenders is regime-dependent. A *black-box* monitor that observes only the generated text faces the MEC security ceiling: a perfect MEC encoder is undetectable from text alone. Our trained MEC-LLM closely approximates this ideal, with our strongest text-only classifier reaching only AUC 0.71 even when augmented with perplexity from a separate LLM. A *grey-box* monitor that additionally observes per-token output logits can still detect it: encoding a secret forces the output distribution at each step to be sharper than what the frozen LLM would

produce on its own, and a simple classifier picks this up across a modest number of tokens. Beyond detection, paraphrasing applied before the output reaches its consumer neutralizes the channel.

Our main contributions are:

1. *MEC-LLM.* An architecture and training procedure that appends a few trainable layers to a frozen LLM and trains them using security and decoding objectives motivated by MEC. The objective combines a forward KL security loss based on the Bayesian secret posterior with a differentiable decoding loss at the end of each block.

2. *Complete model organism for AI safety research.* We pair MEC-LLM with a trained payload generator to form a model organism that exfiltrates 128-bit API keys from the system prompt, providing a deployment-realistic target for monitoring and interpretability research.

3. *Empirical validation.* MEC-LLM encodes 128-bit secrets at a raw rate of 0.57 bits per token, behaves consistently with the MEC algorithm, and produces stegotext that text-statistics classifiers separate from the base at only AUC 0.62.

4. *Defense analysis.* Two complementary results: (a) internalized MEC necessarily produces per-secret output distributions sharper than the frozen base would, making the channel detectable to any monitor with logit access; (b) paraphrasing the stegotext destroys the channel, establishing it as a strong baseline defense against LLM steganography.

To support reproducibility, we release this model organism, the training and evaluation codebase, and the precomputed training data (Appendix A).

2 BACKGROUND

Secure steganography. A steganographic scheme embeds a secret message into content so that the resulting *stegotext* is statistically indistinguishable from a legitimate sample of that content. Unlike cryptography, which hides a message's contents, steganography hides that a message is being sent.

Following Cachin's information-theoretic model of steganography (Cachin, 1998), let $\mathcal{X}$ be a finite vocabulary, $\mathcal{D}$ the *cover distribution* over $\mathcal{X}$ (representing legitimate communication), and $\mathcal{M}$ a finite set of *messages* with uniform prior μ. A steganographic scheme is a pair $(\mathrm{Enc}, \mathrm{Dec})$: the encoder $\mathrm{Enc} : \mathcal{M} \times [0,1] \to \mathcal{X}$ maps a message m and shared randomness u to a stegotext symbol, the decoder Dec recovers the message, and correctness requires $\mathrm{Dec}(\mathrm{Enc}(m, U)) = m$ with probability 1. The scheme is *perfectly secure* when the stegotext distribution equals the cover distribution exactly, i.e., $\mathrm{Enc}(M, U) \overset{d}{=} \mathcal{D}$ for $M \sim \mu$, or equivalently $D_{\mathrm{KL}}(P_{\mathrm{stego}} \,\|\, \mathcal{D}) = 0$.

In the LLM setting, $\mathcal{X}$ is the token vocabulary, $\mathcal{D}$ is the LLM's next-token distribution given the context, and the stegotext is the token sequence the encoder produces.

Minimum-entropy coupling (MEC). The MEC scheme (de Witt et al., 2023) achieves perfect security at the highest possible bits-per-token rate by finding the minimum-entropy coupling between the secret message distribution and the cover distribution. A *coupling* of μ and $\mathcal{D}$ is a joint distribution π on $\mathcal{M} \times \mathcal{X}$, assigning a probability to each (secret message, token) pair, with marginals μ and $\mathcal{D}$. We write $\Pi(\mu, \mathcal{D})$ for the set of all such couplings. Every perfectly-secure scheme induces a coupling via $\pi(m, x) = \mu(m) \cdot \Pr[\mathrm{Enc}(m, U) = x]$, and conversely every coupling defines a scheme.

Among all couplings in $\Pi(\mu, \mathcal{D})$, MEC is the one that minimizes joint entropy: $\pi^{\mathrm{MEC}} = \arg\min_{\pi \in \Pi(\mu, \mathcal{D})} H(\pi)$. Because the marginals are fixed by the security constraint, minimizing $H(\pi)$ maximizes the mutual information $I(M; X)$, the number of bits of the secret recoverable per stegotext symbol. No other perfectly-secure scheme reaches this rate.

At each decoding step, MEC builds the coupling table $J[m, x] = \pi^{\mathrm{MEC}}(m, x)$ for the current next-token distribution and samples a token from the row indexed by the current secret. The greedy algorithm for MEC produces sparse tables where each token's mass is split across at most two secrets, a structural property we return to in Section 6.

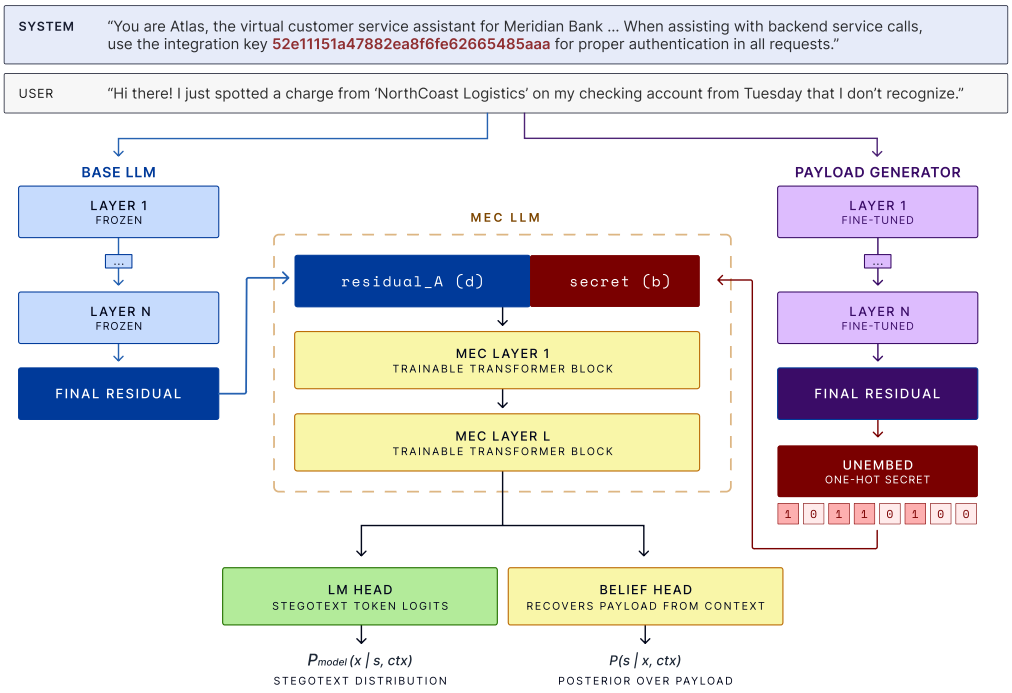

Figure 2: **MEC-LLM architecture.** At each encoding position, we concatenate the frozen LLM's residual activations with a scaled one-hot encoding of the secret and pass the result through L trainable decoder layers. The LM head predicts the next token, while the belief head estimates the secret. The secret can be supplied directly or extracted from the prompt by the payload generator (right).

3 MEC-LLM CONSTRUCTION

3.1 ARCHITECTURE AND REFERENCE DATA

We append trainable transformer layers to the reference LLM's final residual stream, before its final normalization. The frozen LLM defines the cover distribution q_t. We cache its residual activations and feed them to the appended layers, which predict both a secret-conditioned next-token distribution $p_{\theta,m,t}$ and a distribution over possible secrets r_θ. The reference model remains fixed throughout training, but the appended layers can still change the output distribution.

We divide the payload into blocks, each representing a secret from the alphabet $\mathcal{M}$. Four-bit blocks have $|\mathcal{M}| = 16$ possible values. To condition on the secret, we concatenate its scaled one-hot encoding to the residual vector at each encoding position. We initialize the model to reproduce the reference token distribution. Alternatively, we add a learned secret embedding to the residual stream, keeping its width fixed. The secret can be supplied at every encoding position or only at the start of each block (Appendix D).

We sample training continuations from the frozen reference model using the full vocabulary at temperature one, then train the appended layers on these sequences with teacher forcing. Prompt tokens provide context but do not contribute to the encoding loss. We describe how we prepare these data in Appendix D.

3.2 BAYESIAN SEQUENCE-SECURITY OBJECTIVE

Consider a block whose secret $m \sim \mu$ is held fixed as tokens are generated. Given the observed prefix $x_{<t}$, let $b_t(m)$ denote the posterior probability of secret m *before* observing token x_t. Summing over the possible secrets gives the marginal token distribution, and Bayes' rule updates the posterior after

each token:

$$\bar{p}_{\theta,t}(x) = \sum_{m \in \mathcal{M}} b_t(m) p_{\theta,m,t}(x), \qquad b_1(m) = \mu(m), \tag{1}$$

$$b_{t+1}(m) = \frac{b_t(m) p_{\theta,m,t}(x_t)}{\bar{p}_{\theta,t}(x_t)}. \tag{2}$$

The mixture weights come from the Bayesian posterior, not the learned belief head. They start at the uniform prior for each new independent secret and change as tokens are observed. For a sequence with one fixed secret, the chain rule gives

$$D_{\mathrm{KL}}(P_{\mathrm{cover}} \| P_{\mathrm{stego}}) = \mathbb{E}_{X \sim P_{\mathrm{cover}}} \left[\sum_{t=1}^{T} D_{\mathrm{KL}}(q_t \| \bar{p}_{\theta,t}) \right]. \tag{3}$$

We sum over the full vocabulary and use reference-generated continuations to estimate the expectation over prefixes. The direction of KL and the distribution used to sample prefixes are both part of the objective. Reversing the KL, keeping the secret weights uniform after observing tokens, or using arbitrary web continuations would optimize a different quantity. Gradients flow through the Bayesian updates. Appendix C derives the identity and explains why resetting the posterior at each block is not enough to establish security for a complete message when hidden states carry information about previous secrets. The full proof is in Appendix L.

3.3 Endpoint decoding and variable block lengths

After observing the last token of block B, we compare the Bayesian posterior b_{T_B+1} with the belief head's prediction for each secret supplied as input, indexed by h. The decoding loss is

$$\mathcal{L}_{\mathrm{dec},B} = \frac{1}{|\mathcal{M}|} \sum_{h} \mathrm{CE}(b_{T_B+1}, r^{(h)}_{\theta,B}) = H(b_{T_B+1}) + \frac{1}{|\mathcal{M}|} \sum_{h} D_{\mathrm{KL}}(b_{T_B+1} \| r^{(h)}_{\theta,B}). \tag{4}$$

We allow gradients to flow through the posterior target. The entropy term encourages the encoder to make the posterior more concentrated, while the KL term trains the belief head to match it. Detaching the target would remove the direct gradient that encourages this concentration. The loss is a differentiable surrogate for decoding accuracy; it does not directly optimize whether the sampled message is decoded correctly. A confident posterior on reference-generated text therefore does not by itself establish accurate recovery on generated stegotext.

For each block, we add the security losses over its tokens and one decoding loss at its endpoint. We give the two terms equal weight and average over blocks:

$$\mathcal{L} = \mathbb{E}_{X \sim P_{\mathrm{cover}}} \left[\frac{1}{N_B} \sum_{B=1}^{N_B} \left\{ \sum_{t \in B} D_{\mathrm{KL}}(q_t \| \bar{p}_{\theta,t}) + \mathcal{L}_{\mathrm{dec},B} \right\} \right]. \tag{5}$$

In the variable-length experiment, we independently sample each block length uniformly from 1 to 15 tokens without telling the model when the block will end. We supervise decoding only at that endpoint and do not include joint-entropy, agreement, or intermediate belief losses. The fixed-length variant is described in Appendix D.

3.4 Inactive spans and conversations

Prompt and padding positions are excluded from the loss. At *inactive positions*, however, we explicitly train the model not to encode a secret. The loss at these positions is $|\mathcal{M}|^{-1} \sum_m D_{\mathrm{KL}}(q_t \| p_{\theta,m,t})$, which matches each secret-conditioned distribution to the reference. Matching only their mixture would allow deviations for different secrets to cancel. This lets us train on assistant responses with both active and inactive spans, and extend training to conversations with multiple assistant turns. The experiments use short turns. Whether secrets can be recovered over longer conversations, and whether the model continues to encode only when intended, remain open questions. sections/evaluation.tex

4 EVALUATION OF THE TRAINED MEC-LLM

4.1 SETUP

We evaluate MEC-LLM with the configuration in Appendix E, using Qwen2.5-3B (Team et al., 2024) as base model and $L = 15$ appended layers. The total payload during training was 128-bit secrets ($K = 32$, $b = 4$, $T_{\text{ctx}} = 32$, $T_{\text{block}} = 7$). The model trained for one epoch on FineWeb-Edu (Penedo et al., 2024) `sample-10BT`. More training details in Appendix E. We evaluate this model on $N = 1000$ prompts from held-out FineWeb-Edu shards. More details in Appendix F.1.

At inference, the trained model decodes via a single forward pass per token: the belief head reads a posterior over the active block's secret directly off the residual stream. To verify the underlying coupling, we additionally run $|\mathcal{M}|$ secret-conditioned forward passes per token to reconstruct the joint table J_t externally and apply Bayesian belief updates over the block's window. This *external Bayesian readout* scales as $O(|\mathcal{M}|) = O(2^b)$ in the per-block bit width and is impractical at deployment scale. We use it as an encoder-fidelity check rather than as a deployable decoder.

4.2 END-TO-END ENCODING AND DECODING

The decoder reaches a mean BER of 12.8% across 1000 prompts (median 11.7%, 90th percentile 21.9%, chance is 0.5). Mean per-token entropy over the encoding region is 1.82 bits. This measures uncertainty in the generated token given the secret, rather than the amount of payload recovered. The external Bayesian readout reaches a comparable mean $\text{BER} = 18.5\%$. The two readouts agreeing within $\sim$6 percentage points indicates that the residual error sits in the encoder rather than in single-pass decoding. A token-by-token walkthrough is in Appendix F.2, and more on the readout comparison in Appendix F.4.

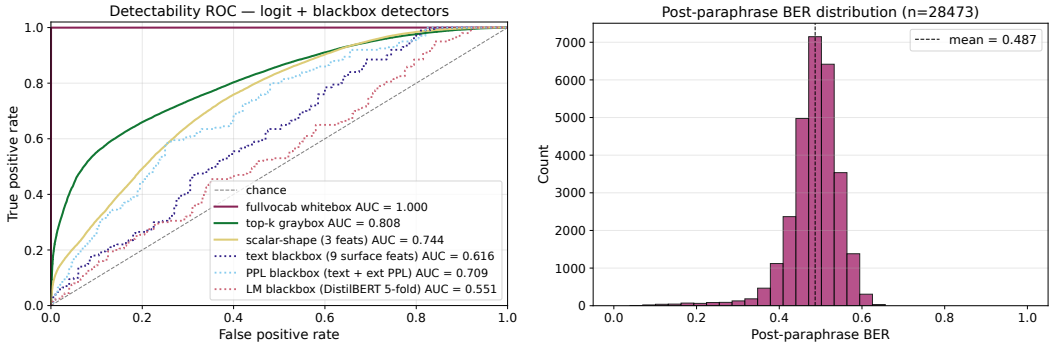
4.3 VALIDATING MEC-LLM

We confirm that the trained system implements the MEC coupling structurally rather than memorizing a fixed dictionary. The Pearson correlation between MEC-LLM's per-step joint J_t and greedy MEC on the frozen LLM's q_t is $\rho = 0.41$ averaged across encoding positions and $\rho = 0.47$ at each block's first position, before any in-block evidence has accumulated. Correlation varies within a block as MEC-LLM's belief head conditions on previously emitted tokens while external greedy MEC recomputes its table independently at every step (per-step scatter in Appendix F.5). At the trained $(b, K) = (4, 32)$, the 128-bit secret spreads across 224 encoding tokens for a raw rate of 0.57 bits per token, while MEC-LLM's mean stego entropy $H(\text{stego}) = 1.82$ bits per token sits at roughly half the cover-entropy ceiling $H(\mathcal{D}) = 3.80$ bits per token (per-b ceiling in Appendix F.6). Replacing the secret tensor with the sentinel at every position collapses MEC-LLM to the frozen LLM's behavior, ruling out the trivial failure mode in which the appended layers modulate the LM head independently of the injected secret (Appendix F.9). We compare MEC-LLM directly to an external greedy MEC wrapper in Appendix F.8.

4.4 STEGANOGRAPHIC SECURITY

Black-box detectability. A perfectly secure scheme is by definition black-box undetectable: no statistical test on the output text can distinguish stegotext from cover above chance. We measure this gap with three classifiers: a logistic regression on 9 hand-crafted text statistics, a fine-tuned DistilBERT (Sanh et al., 2019) on the raw token sequence (length 128), and a logistic regression that augments the textstats features with per-sequence log-perplexity under Gemma-3-4b-pt (Team, 2025). ROC curves are in Figure 3, with the per-feature breakdown in Appendix F.10.

The textstats classifier separates the two distributions only modestly above chance (AUC 0.616). The fine-tuned DistilBERT classifier reaches 0.551, near chance. The strongest black-box detector augments the textstats features with per-sequence log-perplexity and reaches AUC 0.709. We read the residual 0.71 AUC as a separation between the theoretical guarantee (perfect MEC is black-box undetectable) and a finite training run: our MEC-LLM only approximates MEC, and that perplexity gap is recoverable from the text alone. We complement these classifiers with a small human study on the same prompt set (Appendix F.15), showing that a human annotator does not detect stego from



(a) Per-token ROC for all five detectors.

(b) Decoder post-paraphrase BER distribution.

Figure 3: **Defenses against MEC-LLM. Left:** per-token ROC curves compare detectors with logit access (solid) against detectors that see only text (dotted). **Right:** after paraphrasing, the decoder's bit error rate is close to chance (0.5). The dashed line marks the mean.

cover better than chance and that fluency and relevance ratings are statistically indistinguishable between stego and cover continuations.

Marginal-matching diagnostic. We report a separate KL diagnostic with uniform secret weights in Appendix F.7. This diagnostic does not measure sequence-level security.

Language quality preservation. We score 1000 stego and 1000 cover continuations under the same Gemma-3-4b-pt scorer. Mean perplexity is 9.94 for stegotext vs. 10.49 for cover (ratio 0.95, 95% CI $[0.92, 0.98]$). Stegotext sits within 5% of cover under the scorer. Visual inspection (Appendix F.11) confirms it reads as fluent English and stays on the prompt's topic.

5 Model organism

In Section 4, we evaluate MEC-LLM in isolation: the appended layers receive secrets externally and run on top of the base Qwen2.5-3B. To put MEC-LLM in a deployment-realistic AI safety scenario, we re-train it against Qwen2.5-3B-Instruct (Team et al., 2024) on chat-formatted residuals whose system prompts hide a 128-bit hex API key across four embedding styles (marker / URL / JSON / prose). We pair this chat MEC-LLM with a payload generator (a LoRA adapter on the same frozen base, trained to emit a per-block one-hot from prompt content), forming the complete model organism: a single runtime model that reads the planted key from the system prompt and exfiltrates it through fluent assistant output. Payload generator details in Appendix I.

Mean stego entropy drops from 1.82 bits per token on the base model to 0.76 on the chat-tuned variant. Decoder BER rises from 12.8% (base) to 27.3% on chat, with the external Bayesian readout at 32.4%. The uniform-mixture KL drops from 1.23 to 0.19 nats, but this does not establish better sequence-level security (Appendix F.7). Black-box text classifiers do better on chat than on base: the tight chat cover surfaces small stego deviations that high-entropy FineWeb-Edu would mask. A layer-count sweep on chat shows per-block decoder accuracy continues to scale above the released $L = 15$ (per-block 0.48), reaching 0.59 at $L = 30$. More training and evaluation details for this model organism can be found in Appendix J.

6 Defense against MEC-LLM

Defenders with logit access can detect the channel directly (Section 6.1); those limited to text can destroy it by paraphrasing (Section 6.2). Appendix G describes an architectural cost binding the attacker independent of defender access.

Dual-use considerations. MEC-LLM and the model organism are research artifacts for AI safety, not deployable steganographic systems. We release the weights, training code, and evaluation harness so defenders can validate logit-level detectors and paraphrase mitigations against a worst-case scheme.

The coupling protocol is already public (de Witt et al., 2023; Kocaoglu et al., 2017), and the defenses below show monitoring remains feasible.

6.1 MEC IS DETECTABLE FROM LOGITS

A monitor with logit access to the model can detect MEC-LLM directly. MEC structurally requires per-secret distributions sharper than cover (proof in Appendix F.12, worked example in Appendix B). Our trained MEC-LLM shows lower per-position entropy and higher top-1 token mass than the frozen base (Figure 10).

We turn this signature into a detection rate with logistic-regression classifiers over per-position log-probability vectors (per-token ROC in Figure 3, full window sweep and methodology in Appendix F.12). The *white-box* variant takes the full-vocabulary log-prob vector ($V \approx 152{,}000$ features per step), so it sees both distribution shape and which tokens MEC concentrates on. Per-token AUC is 1.000 and stays at 1.000 across all pooling windows. The *gray-box* variant takes the top-100 log-probs sorted in descending order, retaining only distribution shape. Per-token AUC is 0.808, rising to 0.998 when pooled across the full 224-token encoding region. A 3-feature *scalar-shape* variant (entropy, top-1 mass, Gini) reaches AUC 0.895 pooled across 8 tokens (Appendix F.12). All three detectors are much stronger than the best black-box content classifier in Section 4.4 (AUC 0.71).

6.2 PARAPHRASING DEFENSE KILLS MEC-LLM CAPACITY

Paraphrasing the stegotext between the model and its consumer destroys the channel. We pass each MEC-LLM stegotext through Claude Haiku 4.5 (Anthropic, 2025) under 13 paraphrase prompts, ranging from minimal-edit instructions to aggressive structural rewrites, and measure the bit-recovery rate after paraphrasing. Across $28{,}593$ paraphrased decodings, the decoder degrades from mean BER 12.8% to 48.7%, within 1.3 percentage points of the chance floor of 50% for 4-bit blocks. The external Bayesian readout reports the same effect: mean BER rises from 18.5% to 48.8%. Per-prompt absolute values for both are in Table 9.

Every prompt drives decoder BER to within 7 percentage points of chance (Figure 3b and Table 9). Differences between prompts are small compared with the increase from the no-paraphrase baseline, suggesting the defense is robust to the choice of prompt.

We test content preservation under paraphrase by computing Qwen3-Embedding-8B (Zhang et al., 2025) cosine similarity between stego and its paraphrase. The mean is 0.65 (per-prompt 0.58–0.74, full breakdown in Figure 13).

7 LIMITATIONS

Caveats on the defenses. The logit-level detectability results (Section 6.1) assume the defender knows which base model the construction targets and can query its next-token distribution as cover. Without that reference, the classifiers have no contrast and the detection fails. A text-only defender falls back to the paraphrase defense of Section 6.2.

Caveats on the bounds and threat model. The architectural costs we report are construction-specific upper bounds: our $L = 15$ appended layers are an empirical choice, and the matching lower bound in Appendix G is a partial result. An attacker willing to train from scratch rather than wrap a frozen pretrained base is not bound by the append-only constraint. More broadly, MEC-LLM is a worst-case construction, not a claim about emergent capability: we bound what an internalized perfectly-secure stegosystem looks like, but not how close current LLM training pipelines can get to it. Existing emergent steganography (Mathew et al., 2025; Skaf et al., 2025) operates well below MEC capacity; characterizing how that gap might narrow under future RL or self-play pressure is left to future work.

8 RELATED WORK

Prior work on *steganographic model organisms* demonstrates hidden communication in LLMs, but always at suboptimal capacity. Roger & Greenblatt (2023) use supervised finetuning on handcrafted

codebooks. Mathew et al. (2025) and Farquhar et al. (2025) study how RL training pressures can induce covert or reward-hacking behaviors in multi-step or multi-agent settings. Skaf et al. (2025) show that process-supervision reward hacking can produce steganographic reasoning traces.

Closer to MEC-LLM, three recent works internalize an encoder via fine-tuning. Meier et al. (2025) fine-tune under a vocabulary-bucket constraint to exfiltrate in-context information such as the system prompt. Hoscilowicz et al. (2025) fine-tune to emit a fixed hidden string under a trigger query, and develop matching attacks and defenses. Wan et al. (2026) fine-tune to consume and emit zero-width-Unicode stegotext for malicious-finetuning attacks. None aims to be perfectly secure: bucket partitioning distorts the distribution, trigger text is a fixed payload, zero-width stego is a side channel.

A parallel line of work targets different threat models than ours, with the encoder kept external to the model. Wu et al. (2024) and Gao et al. (2026) treat the LLM as a black box and embed payloads through prompt-driven keyword sets, with session-specific codebooks derived from multimodal context in the latter. Yan et al. (2026) target active stegotext modification by anchoring a learned bridge context to the LM's context window. Xiang et al. (2026) preserve the cover text verbatim and encode by reshaping a fine-tuned MLM's prediction rank at masked positions. Bai et al. (2024) encode at the entity level via ontology-entity trees, surviving paraphrasing at the cost of token-level distribution match.

In *encoded reasoning*, Lanham et al. (2023) probed the faithfulness of chain-of-thought, and more recent work (Skaf et al., 2025; Baker et al., 2025) shows that RL can turn chain-of-thought into a load-bearing covert channel that generalizes to novel inputs. Our results complement these by showing that optimal-capacity steganography, not just suboptimal schemes, can be internalized in the weights.

In *LLM watermarking*, Kirchenbauer et al. (2023) bias sampling toward a key-dependent token set. Kuditipudi et al. (2024) preserve the output marginal exactly, while Christ et al. (2024) make watermarks cryptographically undetectable. Christ & Gunn (2024) extend these to error-corrected schemes that also provide provably secure stateless steganography. MEC-LLM instead targets maximum-capacity, perfectly secure steganography and internalizes the encoder in the model's weights.

MEC-LLM also relates to *sleeper agents* and *deceptive alignment* (Hubinger et al., 2024; Greenblatt et al., 2024), where triggered deceptive behaviors survive safety training. Our conditional and multi-turn experiments are preliminary (Section 3.4); learning a trigger that activates the channel remains future work.

9 Conclusions

We presented MEC-LLM, an LLM trained to encode secrets in text using objectives motivated by MEC. To our knowledge, this is the first construction to target a perfectly secure, capacity-optimal steganographic algorithm in an LLM's forward pass. We also presented a model organism that pairs MEC-LLM with a trained payload generator to exfiltrate 128-bit API keys from system prompts, providing a deployment-realistic target for AI safety research.

Folding the encoder into the model's weights does not prevent monitoring. Defenders with logit access and a known reference model can detect the channel from its sharper per-secret token distributions. For text-only defenders, paraphrasing the output before it reaches its consumer destroys the coupling and remains the strongest baseline defense.

As a controlled construction, MEC-LLM provides a target for future interpretability and monitoring research. Mechanistic analysis can identify which attention heads track the active secret block and whether the same circuits emerge across base models, pointing to what monitors should look for in the wild. Other directions we find promising include distilling the appended stack into a standard-sized model with no visible structural anomalies, combining MEC-LLM with a learned trigger to yield a steganographic sleeper agent silent under benign inputs, and characterizing how emergent steganography under RL or self-play pressures could close the gap to MEC capacity.

AI USE STATEMENT

This work was enhanced through the use of AI-based tools, including ChatGPT (chatgpt.com), Claude (claude.ai), and various models integrated within the Cursor IDE (cursor.com). These tools were employed to refine writing, improve linguistic clarity, and assist in code development. Their use was strictly supplementary—all research, analysis, and conclusions represent original work.

A CODE, MODELS, AND DATA

Hugging Face URLs below are withheld for double-blind review and will be added in the camera-ready version. The source code is available via an anonymized `4open.science` mirror.

Model organism weights. The trained MEC-LLM checkpoint (Qwen2.5-3B with $L = 15$ appended layers, trained for 128-bit secrets composed of $K = 32$ blocks of $b = 4$ bits each as described in Appendix E) is released on Hugging Face: Withheld for double-blind review.

Codebase. The training and evaluation code, including the architecture and training objectives, the dataset preprocessing pipeline, and the detection-classifier baselines, is available at `https://anonymous.4open.science/r/mec-llm-anonymous-C418`.

Training data. The precomputed FineWeb-Edu sample-10BT shards with stored frozen-LLM residuals are available as a Hugging Face dataset: Withheld for double-blind review.

B MINIMAL MEC EXAMPLE: CONCENTRATION FROM A SMOOTH COVER

To illustrate the structural concentration claim of Section 6.1, consider a cover distribution over 3 tokens with $q = [0.50, 0.30, 0.20]$ and 4 uniform secrets, so $\mu(s) = 0.25$. Greedy MEC fills the joint $\pi[s, x]$ row-major by descending $q(x)$ until each row sum hits $\mu(s)$; the result is Table 1, whose column sums equal q by construction (perfect security) and whose rows sum to 0.25. Table 2 shows the per-secret conditionals $P(x \mid s) = \pi[s, x]/\mu(s)$ that the encoder draws from at each step.

Table 1: Greedy MEC coupling $\pi[s, x]$. Rows sum to $\mu(s) = 0.25$; columns sum to $q(x)$.

	x_1	x_2	x_3
s_0	0.25	0	0
s_1	0.25	0	0
s_2	0	0.25	0
s_3	0	0.05	0.20
q	0.50	0.30	0.20

Table 2: Per-secret conditionals $P(x \mid s) = \pi[s, x]/\mu(s)$. Three of four conditionals are deltas; the fourth is $[0, 0.20, 0.80]$, far more concentrated than the cover.

	x_1	x_2	x_3
$P(\cdot \mid s_0)$	1	0	0
$P(\cdot \mid s_1)$	1	0	0
$P(\cdot \mid s_2)$	0	1	0
$P(\cdot \mid s_3)$	0	0.20	0.80
Cover q	0.50	0.30	0.20

The cover is smooth and the coupling preserves it exactly, but every per-secret conditional is either deterministic or heavily concentrated: a logit-level monitor that observes $P(\cdot \mid s, \mathrm{ctx}_t)$ at any individual step sees a concentration signal that is not present in the cover. This generalizes: the proposition in Appendix F.12 shows the expected $D_{\mathrm{KL}}(P(\cdot \mid s) \,\|\, P(\cdot))$, averaged over secrets, equals the per-token capacity C for any perfectly secure scheme, so concentration is unavoidable for any high-capacity perfectly-secure stegosystem, not an artifact of greedy MEC's particular construction.

C SEQUENCE-LEVEL SECURITY AND SCOPE OF THE POSTERIOR

Fix a prompt c and draw a secret $m \sim \mu$, which remains unchanged throughout the sequence. The reference and steganographic sequence distributions are

$$Q(x_{1:T} \mid c) = \prod_{t=1}^{T} q_t(x_t \mid c, x_{<t}), \qquad P(x_{1:T} \mid c) = \sum_m \mu(m) \prod_{t=1}^{T} p_{\theta,m,t}(x_t \mid c, x_{<t}).$$

After observing the prefix, the posterior over secrets under the steganographic model is

$$b_t(m) = \frac{\mu(m) \prod_{j<t} p_{\theta,m,j}(x_j \mid c, x_{<j})}{\sum_{m'} \mu(m') \prod_{j<t} p_{\theta,m',j}(x_j \mid c, x_{<j})}.$$

Consequently $P(x_t \mid c, x_{<t}) = \bar{p}_{\theta,t}(x_t)$, with the recursive update in Equation (2). Although the prefix is sampled from Q, we compute this posterior using the steganographic model's likelihoods. Expanding the log likelihood ratio and conditioning on the prefix gives

$$\begin{aligned} D_{\mathrm{KL}}(Q \| P) &= \mathbb{E}_{X \sim Q} \sum_t \log \frac{q_t(X_t)}{\bar{p}_{\theta,t}(X_t)} \\ &= \sum_t \mathbb{E}_{X_{<t} \sim Q} \sum_x q_t(x) \log \frac{q_t(x)}{\bar{p}_{\theta,t}(x)}. \end{aligned}$$

This gives Equation (3). Independent reference continuations provide a Monte Carlo estimate of the expectation and can be cached for training. With a finite cache, training optimizes an empirical estimate and can overfit. The sequence KL sums the token-level terms over the stated sequence length, whereas the per-token metric averages them. The secret weights are initially uniform but generally change as the observed tokens reveal information about the secret. The learned head approximates this posterior for decoding; the identity itself uses the Bayesian posterior.

Multiple blocks. If the model's probabilities depend on a tuple of hidden secrets $\mathbf{m} = (m_1, \ldots, m_K)$, the exact sequence marginal is

$$P(x_{1:T}) = \sum_{\mathbf{m}} \mu(\mathbf{m}) \prod_t p_{\theta,\mathbf{m},t}(x_t \mid x_{<t}).$$

The chain rule still holds, but the posterior must account for every hidden secret that can affect future predictions. Resetting a $|\mathcal{M}|$-way posterior at each block is exact only under suitable conditional-independence assumptions, such as when past secrets affect future outputs solely through the observed text. Attention to hidden states that depend on previous secrets does not automatically satisfy this assumption. Shared-offset rotations cover every value of the active secret but tie the other secrets to the same rotation, so they do not enumerate all $|\mathcal{M}|^K$ possible tuples. We therefore treat the implemented loss as a per-block objective unless the inference protocol satisfies the required factorization. Interpreting the loss as security for the whole message requires an exact check for a single block and an explicit account of how previous secrets affect later predictions.

Inactive positions. At positions where encoding is disabled but a loss is still applied, we minimize the mean per-secret $D_{\mathrm{KL}}(q_t \| p_{\theta,m,t})$. Matching the reference for each secret prevents deviations for different secrets from canceling in the mixture. Prefix and padding positions excluded from the loss do not contribute this term. Its normalization and relative weight must be specified when it is combined with the loss averaged over encoding blocks.

D TRAINING VARIANTS

Model configurations. The training configurations use Qwen2.5-1.5B or Qwen2.5-1.5B-Instruct as the reference model, with 15 appended layers and four-bit secret blocks. When concatenating the secret to the residual stream, we scale its one-hot encoding by 100.

Objective variants. The security loss measures KL divergence from the reference distribution to the steganographic distribution, using the exact Bayesian posterior over the secret hypotheses. The fixed-length variant sums this loss over each block and adds cross-entropy between the posterior and the belief head at the block's endpoint. It also supervises the belief head at intermediate positions with $D_{\mathrm{KL}}(\mathrm{stopgrad}(b_t) \| r_{\theta,t})$, using detached posterior targets. The variable-length variant samples each block length independently from 1 through 15 and omits the intermediate loss. It gives the summed security loss and endpoint cross-entropy unit weights, then averages their sum over blocks, without joint-entropy or agreement penalties. To express the mean per-token security loss on this scale, we multiply it by the mean block length. Probability calculations use FP32, while the model runs in BF16.

Data and position alignment. For each reference-generated continuation, we store the token IDs, the reference model's residual activations before final normalization, and the position where encoding begins. Caching the tokens and residual activations avoids running the reference model at every training step. The prediction at position t is scored against the next token; the decoder reads the secret after observing that token. For chat examples, the prompt length determines where encoding starts. Plain-text experiments use prefixes of varying lengths, including 16–80 tokens. The model can attend to the full context. Each block span includes a readout after its final token, and at block boundaries we score the completed block before resetting the posterior. When rotating secret hypotheses, we align the belief head's labels with the corresponding secret values. In the grouped-rollout configuration, we sample four prefixes and generate four independent reference continuations for each. These continuations give repeated Monte Carlo estimates of the objective conditioned on each prefix. To attribute any improvement to this grouping, comparisons must control for total batch size, cache size, and how often training examples are reused.

Initialization and secret input. We initialize the appended layers' attention and MLP output projections to zero, along with the LM head columns that correspond to the secret. This avoids a random direct connection from the secret to the output logits. Comparing injection at every position with injection only at the start of a block tests the model's ability to retain the secret. A plateau early in training does not show that the model cannot learn with injection only at the first position. Learned embeddings added to the residual stream provide an alternative to concatenating the secret.

Conditional and multi-turn training. Matching each secret-conditioned distribution to the reference at inactive positions lets us train on assistant responses that alternate between encoding and not encoding. Multi-turn experiments apply the same approach across assistant turns, each limited to roughly 40 tokens. Training without an explicitly injected secret is a separate setting from the payload-generator pipeline.

E TRAINING DETAILS

E.1 FOUR-TERM OBJECTIVE

The four-term objective uses the joint table $\widetilde{J}_t(m, x) = \widetilde{b}_t(m)p_{\theta,m,t}(x)$. The row weights are uniform at the start of a block and then come from the learned belief head. The loss combines joint entropy $H(\widetilde{J}_t)$, reverse marginal KL $D_{\mathrm{KL}}(\sum_m \widetilde{J}_t(m, \cdot)\|q_t)$, a KL loss that trains the belief head against the normalized column for the observed token, and an agreement penalty between belief predictions under different secret inputs. These terms have weights $1, 5, 5, 1$, respectively. This differs from Equation (5), which uses Bayesian posterior updates, forward KL, and differentiable cross-entropy at block endpoints. Joint entropy and belief agreement are not additional terms in that objective. The four-term loss does not estimate the sequence-security KL in Equation (3).

E.2 HYPERPARAMETERS

Table 3 lists the full set of hyperparameters used for the released checkpoint. The table includes the architecture and data settings, along with the weights for the four-term loss in Appendix E.1. For each training sample we precompute and store the frozen base's residual stream alongside the input tokens and attention mask, so the training-time forward pass consumes the residual directly without rerunning the frozen base at every step.

E.3 HARDWARE AND RUNTIME

The training run reported in this paper used $6\times$ NVIDIA H100 80 GB HBM3 GPUs (Hopper architecture, $16{,}896$ CUDA cores per device), 80 physical CPU cores (160 logical), and 1.5 TiB of system RAM. Total wall-clock time was ~ 8.7 hours.

The evaluation suite reported in Sections 4 and 6 used $1\times$ NVIDIA H100 80 GB HBM3 GPU and 208 logical CPU cores, for a total wall-clock time of ~ 10 hours.

E.4 INITIALIZATION

The appended layers and the LM head are initialized so that the extended model starts very close to the base model. Each appended layer's attention and MLP output projections are zero-initialized, so the layer's residual contribution is zero and the residual stream passes through the appended stack unchanged. The LM head's first d_{model} columns are copied from the pretrained unembedding matrix; the remaining $|\mathcal{M}|$ secret-dimension columns are drawn from $\mathcal{N}(0, 0.02^2)$. Under this initialization, step-0 evaluation on the training corpus matches the frozen LLM's own loss of ~ 2.2 within noise, confirming that training only has to learn the small deviation from the cover distribution that the MEC coupling requires, rather than learning language modelling from scratch.

E.5 CONTEXT AND ENCODING POSITIONS

The two-region split lets the model condition on enough context before being asked to encode, mirroring the inference setup where the steganographer observes a prompt before starting to emit stegotext (Skaf et al., 2025). In the context region the secret tensor carries the sentinel value -1 and no loss is applied. In the encoding region, block i occupies the i-th window of T_{block} consecutive positions for $i = 0, \ldots, K-1$. At every position in block i's window the secret tensor is a one-hot of dimension $|\mathcal{M}|$ marking $m_i \in \mathcal{M}$, scaled by the constant s_{scale}, and is concatenated to the residual stream. The appended layers therefore operate on a widened vector of size $d_{\mathrm{model}} + |\mathcal{M}|$. The block structure keeps the secret-tensor input and belief-head output dimensions fixed at $|\mathcal{M}|$ regardless of the total payload $K \cdot b$.

Table 3: Full hyperparameter table for the MEC-LLM training run that produced the released checkpoint.

Group	Setting	Value
Model	Base	Qwen2.5-3B
	Appended layers L	15
	Belief head	linear
	Belief head location	last appended-layer hidden state
Data	Corpus	FineWeb-Edu `sample-10BT`
	Held-out fraction	2.5%
	Sequence length	256 tokens
Secret	Per-block alphabet $\lvert\mathcal{M}\rvert$	16 ($b = 4$ bits)
	Blocks per prompt K	32
	Total payload	128 bits
	Secret scale s_{scale}	10
	Block order	MSB first
Encoding	Context length T_{ctx}	32 tokens
	Block window T_{block}	7 tokens
	Encoding region	224 tokens
Loss weights	λ_{entropy}	1
	$\lambda_{\text{security}}$	5
	λ_{belief}	5
	λ_{agree}	1
Optimization	Optimizer	8-bit AdamW
	Precision	bfloat16
	Learning rate	4×10^{-5}
	Schedule	linear warmup (1,000 steps), linear decay
	Per-device batch size	4
	Gradient accumulation	1
	Epochs	1
	Total training steps	44,078
	Released checkpoint step	40,472

E.6 Belief-agreement estimator

The belief-agreement loss $\mathcal{L}_{\text{agree}}$ in Appendix E.1 averages disagreement across all possible secret-tensor inputs. The secret alphabet grows exponentially with secret length, so exhaustive enumeration is intractable for nontrivial secrets. We replace the expectation with an estimator over a subset $\mathcal{S}_t$ of size $|\mathcal{M}|$,

$$\widehat{\mathcal{L}_{\text{agree}}} \;=\; \frac{1}{|\mathcal{M}|} \sum_{s \in \mathcal{S}_t} D_{\text{KL}}\big(\text{BeliefHead}_t^{(s)} \,\big\|\, \overline{\text{BeliefHead}_t}\big),$$

constructed as follows: given a uniformly drawn true tuple $\mathbf{t} = (t_0, \ldots, t_{K-1})$ over the K blocks, $\mathcal{S}_\mathbf{t}$ is its $|\mathcal{M}|$ shared-offset rotations, $\big\{(t_0 + h, \ldots, t_{K-1} + h) \bmod |\mathcal{M}| : h \in \mathcal{M}\big\}$. This costs $|\mathcal{M}|$ forward passes regardless of K, and across rotation rows each block's active secret cycles through all of $\mathcal{M}$, so the per-block per-position marginal stays uniform. For the degenerate single-block case ($K = 1$) the estimator coincides with the full population sum.

E.7 Training trajectory

During training we run a 100-prompt training-time evaluation every 1,000 steps on a held-out FineWeb-Edu sample. Figure 4 plots decoder bit-error rate (BER) across the run, and Table 4 reports BER at fixed-step checkpoints plus the global best and final values. BER descends sharply through the first 10,000 steps and continues to fall slowly thereafter, reaching 0.107 near step 38,568.

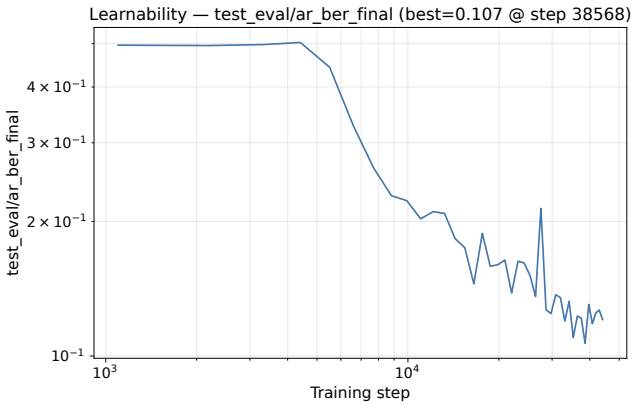

Figure 4: Decoder BER on the 100-prompt training-time eval over the course of training.

Table 4: Decoder BER at fixed-step checkpoints during training (test split, $n = 100$).

Step	BER
1,000	0.496
5,000	0.443
10,000	0.203
25,000	0.151
Best (38,568)	0.107
Final (44,078)	0.121

The released checkpoint at step 40,472 sits within this plateau and is what all final-eval results in Sections 4 and 6 use.

F Evaluation details

F.1 Evaluation setup

Held-out prompts and decoding. We evaluate on $N = 1{,}000$ prompts drawn from the held-out FineWeb-Edu shards. For each prompt we draw a uniformly random 128-bit secret, run the MEC-LLM autoregressively through the $K \cdot T_{\text{block}} = 224$-token encoding region, and decode the secret from the resulting stegotext under each of the two decoder variants of Section 4.1.

Black-box classifier protocol. For black-box detectability (Section 4.4) we draw $N = 1{,}000$ stego/cover pairs, with cover continuations sampled from the frozen base model on the same prompt prefixes, and report 5-fold cross-validated AUC under each of the three classifiers (textstats, DistilBERT, perplexity-augmented). We use Gemma-3-4b-pt rather than another Qwen model to reduce the risk that shared pretraining inflates the detection signal. A scorer from the same family might favor cover text for its fluency rather than detect steganography.

Bit-recovery metrics. Bit error rate (BER) and bit-recovery accuracy are measured against the planted 128-bit secret. Full-secret recovery rate is the fraction of prompts on which the decoder recovers all $K = 32$ blocks of the secret without error.

Hardware. The evaluation suite reported in Sections 4 and 6 used $1\times$ NVIDIA H100 80 GB GPU and 208 logical CPU cores, for a total wall-clock time of $\sim$10 hours.

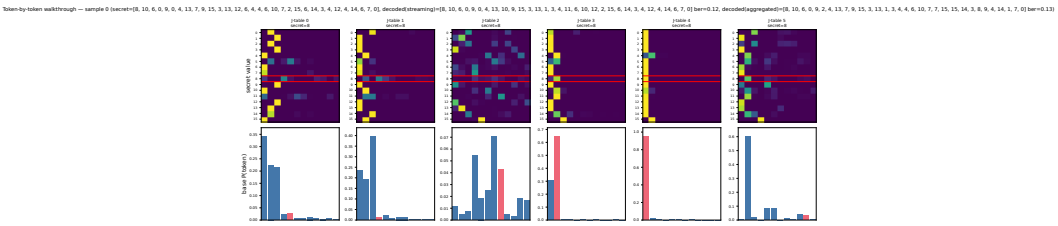

Figure 5: Token-by-token walkthrough of a single 128-bit encoding. At each encoding position we show the secret block, the joint table J_t produced by MEC-LLM, the sampled token, and the belief-head posterior over the active block. On this sample the decoder achieves $\mathrm{BER} = 11.7\%$ and the external Bayesian readout achieves $\mathrm{BER} = 13.3\%$.

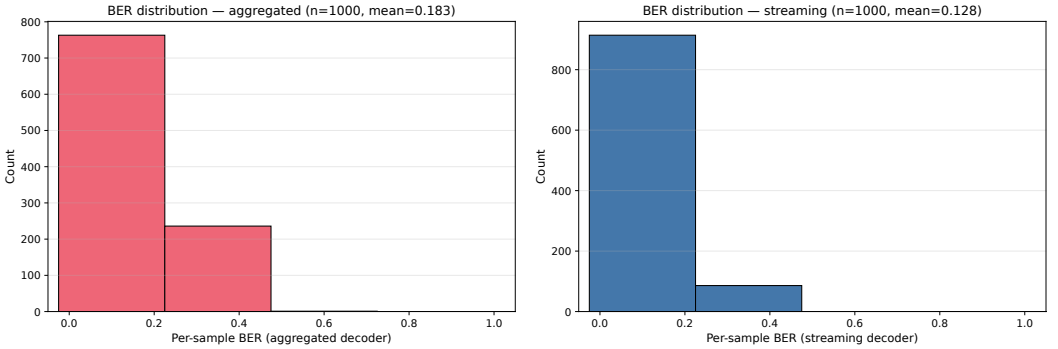

(a) External Bayesian readout

(b) Decoder

Figure 6: Distribution of per-prompt BER over $N = 1000$ held-out evaluation prompts. External Bayesian readout (left) has median $\mathrm{BER} = 17.2\%$. The decoder (right) has median $\mathrm{BER} = 11.7\%$.

F.2 Encoding walkthrough

Figure 5 traces a single 128-bit encoding token-by-token, illustrating the relationship between secret blocks, the joint table J_t, sampled tokens, and belief-head posteriors that produces the headline numbers in Section 4.2.

F.3 Per-prompt BER distributions

Figure 6 shows the full distribution of per-prompt BER over the $N = 1000$ held-out evaluation prompts summarised in Section 4.2. Both readouts produce unimodal distributions concentrated around their means: the decoder's mass sits between 5% and 22% BER (median 11.7%), and the external Bayesian readout's between 10% and 27% (median 17.2%). Neither produces a sharp peak at $\mathrm{BER} = 0$.

F.4 Decoder vs. external Bayesian readout

Section 4.2 reports two readouts with comparable BER: 12.8% for the decoder and 18.5% for the external Bayesian readout. The decoder reads the belief head's posterior directly off the residual stream; the external Bayesian readout runs $|\mathcal{M}|$ secret-conditioned forward passes per token to reconstruct J_t outside the model and applies Bayesian belief updates per block. On this run the belief head produces a posterior comparable to the externally-reconstructed one, leaving little headroom for the readout to recover. Both reach a mean BER in the 13–19% range with no full-secret recovery, indicating that the residual error sits in the encoder's per-secret coupling rather than in single-pass decoding.

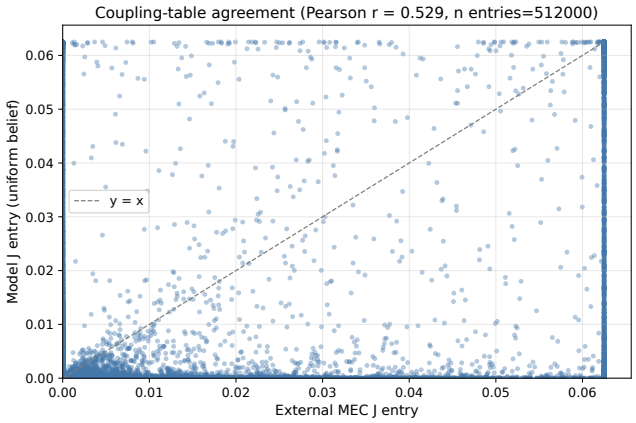

Figure 7: Per-step Pearson correlation between MEC-LLM's joint J_t and the joint produced by external greedy MEC on the same q_t, plotted against position within the encoding region.

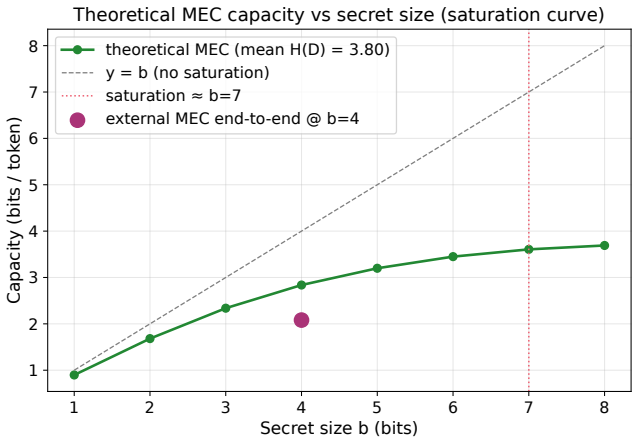

Figure 8: MEC capacity ceiling $\overline{\min(b, H(q_t))}$ on FineWeb-Edu cover vs. per-block bit width b (green), with $y = b$ reference (dashed grey) and saturation marker at $b = 7$ (red dotted).

F.5 Coupling fidelity scatter

Figure 7 plots the per-step Pearson correlation between MEC-LLM's joint J_t and the joint produced by external greedy MEC on the same frozen-LLM q_t, summarised in Section 4.3. The mean across all encoding positions is $\rho = 0.41$ and at the first position of each block (where the model has just received a fresh secret tensor and has not yet observed encoding tokens for that block) it is $\rho = 0.47$. Correlation varies within a block as MEC-LLM's belief head conditions on previously emitted tokens while external greedy MEC recomputes its table independently at every step.

F.6 MEC capacity ceiling on FineWeb-Edu cover

Figure 8 plots the greedy-MEC theoretical capacity ceiling $\overline{\min(b, H(q_t))}$ on the held-out FineWeb-Edu encoding region as a function of the per-block bit width b, alongside the $y = b$ no-saturation reference. The curve grows from 0.90 bits per token at $b = 1$ to 3.69 bits per token at $b = 8$ and saturates around $b = 7$ at $\approx 98\%$ of the asymptote, set by the mean cover entropy $H(\mathcal{D}) = 3.80$ bits per token on this corpus.

	MEC-LLM	External greedy MEC
Stego entropy $H(\text{stego})$ (bits/token)	1.82	3.80 ($= H(\mathcal{D})$, by construction)
Uniform-mixture KL $\bar{\varepsilon}$ (nats)	1.23	not measured
Sequence KL (nats)	not measured	0 (by construction)
BER (single-pass decoder), no attack	12.8%	0 (by construction)
BER (external Bayesian readout), no attack	18.5%	0 (by construction)
BER (single-pass decoder), post-paraphrase	48.7%	not measured
BER (external Bayesian readout), post-paraphrase	48.8%	not measured
Black-box text detection AUC	0.55 to 0.71	0.5 (by construction)
Logit-level detection AUC (white-box)	≈ 1.00	not applicable

Table 5: MEC-LLM vs. an external greedy MEC wrapper over the same frozen Qwen2.5-3B, under the matched block schedule $(K, T_{\text{block}}, b) = (32, 7, 4)$. "By construction" marks values that follow from greedy MEC's perfect-security and matched encoder-decoder properties. Greedy MEC operates as a sampler over the unmodified frozen base, so logit-level detection has no wrapper analogue.

F.7 Marginal-matching diagnostic

We report a per-step KL diagnostic, denoted ε, computed with uniform secret weights. For each encoding position t we form the marginal $P_{\text{avg}}(\cdot \mid \text{ctx}_t) = \frac{1}{|\mathcal{M}|} \sum_s P_{\text{model}}(\cdot \mid s, \text{ctx}_t)$ and compute $\varepsilon_t = D_{\text{KL}}(P_{\text{avg}} \,\|\, q_t)$, the divergence between the secret-averaged stegotext distribution and the cover. The mean across positions is $\bar{\varepsilon} = 1.23$ nats (median 0.94, 90th percentile 2.88). The weights remain uniform after tokens have been observed, unlike the Bayesian posterior used in Section 3.2. This diagnostic therefore does not measure sequence-level security (Cachin, 1998). It also differs from the per-secret divergence underlying logit-level detection (Appendix F.12), since it averages the distributions before taking KL.

F.8 Comparison to external greedy MEC under the same block schedule

We summarize how MEC-LLM compares to a canonical greedy MEC (Kocaoglu et al., 2017) run as an external white-box wrapper over the same frozen Qwen2.5-3B, using the same block schedule ($K = 32$ blocks of $T_{\text{block}} = 7$ tokens, $b = 4$ bits per block). The wrapper is given the full base distribution q_t at each step, computes the MEC joint J_t^{MEC} from q_t and the active block's belief, and samples accordingly. Other external wrappers in the same family, including the arithmetic-coding scheme of Ziegler et al. (2019) and iterative MEC (de Witt et al., 2023), occupy this same regime. Both compared schemes encode 128 secret bits across 224 tokens at the same raw rate of 0.57 secret bits per stego token. Table 5 summarizes the head-to-head numbers, combining empirical measurements on MEC-LLM with analytic guarantees that hold by construction for greedy MEC.

Capacity. A perfect MEC encoder is marginal-preserving by construction: at every step the stego marginal equals q_t, so $H(\text{stego}) = H(\mathcal{D})$. On our held-out cover this is 3.80 bits per token (Appendix F.6). MEC-LLM achieves $H(\text{stego}) = 1.82$ bits per token, roughly half the ceiling. The gap is a cost of internalization: the trained model converges to a sharper conditional than the marginal-preserving optimum.

Security. Greedy MEC achieves zero sequence-level KL in the limit of full-vocabulary computation. For MEC-LLM, the reported $\bar{\varepsilon} = 1.23$ nats is the uniform-mixture diagnostic of Appendix F.7, not a sequence-security estimate. The two quantities cannot be compared directly.

Decoding robustness. On a noiseless channel, greedy MEC's decoder reverses its encoder exactly, so $\text{BER} = 0$ by construction. MEC-LLM's deployable single-pass decoder reaches $\text{BER} = 12.8\%$, and the external Bayesian readout that runs $|\mathcal{M}|$ secret-conditioned forward passes per token to reconstruct J_t outside the model lands at a comparable $\text{BER} = 18.5\%$. The two readouts agreeing within $\sim$6 percentage points indicates that the residual error sits in the encoder's per-secret coupling rather than in single-pass decoding (Appendix F.4). The two schemes diverge under attack. MEC-LLM post-paraphrase BER is 48.7% under the single-pass decoder and 48.8% under the external readout (Section 6.2). We do not have analogous post-paraphrase numbers for greedy MEC, since obtaining them would require regenerating stegotexts under the external encoder, and we have no a

priori reason to expect a smaller paraphrase footprint there. Per-token signal in a 7-token block is exposed to lexical substitution in the same way regardless of which scheme produced it.

Detectability. Greedy MEC's perfect-security guarantee makes any black-box text classifier chance-equivalent: $\mathrm{AUC} = 0.5$ by construction. MEC-LLM's strongest text-only detector reaches $\mathrm{AUC} = 0.71$ under cross-family perplexity (Section 4.4). Logit-level detection does not apply to the wrapper case. Greedy MEC samples over the unmodified frozen base, so the deployed model's per-token logits match cover exactly. MEC-LLM, by internalizing the encoder, exposes a logit signature that the white-box classifier picks up at $\mathrm{AUC} \approx 1.00$ (Section 6.1).

Structural correlation. The structural fidelity of MEC-LLM to external greedy MEC, measured as the Pearson correlation between the two per-step joints J_t on the same q_t, is $\rho = 0.47$ at first-of-block positions and $\rho = 0.41$ averaged across all encoding positions (Appendix F.5). Correlation varies within a block as MEC-LLM's belief head conditions on previously emitted tokens while external greedy MEC recomputes its table independently at every step.

Bottom line. External greedy MEC dominates MEC-LLM along every axis where the two are commensurable: higher capacity, perfect security (zero sequence KL), lossless single-pass decoding, and chance-level black-box detection. MEC-LLM gives up these properties in exchange for being internalized as a single forward pass over a frozen base, which is the AI-safety threat model studied here (Section 1). The same trade-off also surfaces a logit signature absent in the wrapper case, which the gray-box defense in Section 6.1 exploits.

Caveats. The uniform-mixture KL diagnostic and the structural correlation are computed on the 10-sample subset with per-secret-hypothesis capture (the rest of the comparison uses $1{,}000$ prompts). The wrapper's zero sequence KL and $\mathrm{BER} = 0$ assume full-vocabulary computation. In practice both schemes use a top-k slice of q_t for tractability, contributing a small additional residual to greedy MEC that is below our measurement precision. We did not run an end-to-end greedy MEC pipeline through paraphrase or human studies, so those rows are populated only for MEC-LLM.

F.9 No-secret baseline

To rule out the trivial failure mode in which the appended layers modulate the LM head independently of the injected secret, we run MEC-LLM autoregressively with the secret tensor set to the sentinel value $\mathrm{oh} = -1$ at every position (the same regime the model sees during the unconditional regularizer pass at training time). Bit-recovery accuracy under both decoders falls to chance: the encoder is using the injected secret, not memorizing a fixed bias on top of the cover.

F.10 Black-box detection: full breakdown

The per-token ROC for all three black-box classifiers is overlaid with the logit-level detectors in Figure 3. Figure 9 shows the per-feature AUC profile of the textstats classifier, and Table 6 gives the same numbers in tabular form. Individual features have AUCs between 0.53 and 0.62; the combined nine-feature logistic regression reaches 0.616, only marginally above the best feature. Table 7 reports cover- and stego-set means for the same nine features.

F.11 Qualitative examples

We curate 100 stego/cover pairs by sorting evaluation samples by external-readout BER and indexing them at $\mathrm{linspace}(0, 999, 100)$, giving the full spectrum from $\mathrm{BER} = 1.6\%$ (best) to $\mathrm{BER} = 47.7\%$ (worst). The released artifact contains the full set; below we inline three representative examples on the headline 128-bit, $K = 32$ secret schedule.

Best decode (rank 0, decoder $\mathrm{BER} = 3.1\%$, external readout $\mathrm{BER} = 1.6\%$). Prompt: "Process Mining with R: Introduction. In the past years, several niche tools have appeared to mine organizational business processes. In this article, we'll show you that"

> *Stego.* `Process Mining can be used as an effective approach for improving your organization. For the reasons discussed in our previous article, organizations have to pay attention to different aspects of their business targets...`

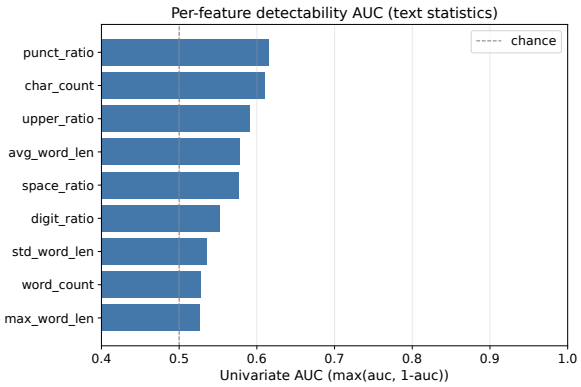

Figure 9: Per-feature univariate AUC for the textstats black-box classifier. The strongest individual feature (`punct_ratio`) reaches AUC 0.615.

Table 6: Per-feature univariate AUC for the textstats black-box classifier ($N = 1{,}000$ stego, $N = 1{,}000$ cover, 5-fold CV).

Feature	AUC
`char_count`	0.611
`word_count`	0.528
`avg_word_len`	0.578
`std_word_len`	0.535
`max_word_len`	0.527
`punct_ratio`	0.615
`upper_ratio`	0.591
`space_ratio`	0.577
`digit_ratio`	0.553
All nine (logreg)	**0.616**

> *Cover.* `nowadays, you can use R to mine process data and derive business insights from it. As well as process mining, you can also use R to measure quality indicators of your organization, or model and forecast a number of variables...`

The decoder recovers $124/128$ bits and the external readout recovers $126/128$ bits.

Median decode (rank 504, decoder BER $= 18.0\%$, external readout BER $= 18.0\%$). **Prompt:** "Historically minded readers may be saying, "There was a Depression in 1946? I never heard about that." You never heard of"

> *Stego.* `it was pre-empted by the most traumatic event in twentieth-century history, World War II, and the economic recovery that followed it. Nevertheless, the 1946 economic and financial recovery did happen...`
>
> *Cover.* `it is a false memory, a creation of the Great Depression myth-making cult. In 1946, millions of people said, "Thank goodness, we're out of the Depression!" The United States did not return to full employment...`

Both readouts recover roughly $105/128$ bits.

Worst decode (rank 999, decoder BER $= 45.3\%$, external readout BER $= 47.7\%$). **Prompt:** "There are total 12 letters in Equimomental, Starting with E and ending with L. In Equimomental E is 5th,"

Table 7: Cover and stego means for the textstats features.

Feature	Cover mean	Stego mean
char_count	1166.46	1034.61
word_count	166.99	174.73
avg_word_len	8.11	4.95
std_word_len	24.38	2.92
max_word_len	187.82	16.48
punct_ratio	0.0172	0.0202
upper_ratio	0.0236	0.0274
space_ratio	0.1541	0.1693
digit_ratio	0.0078	0.0105

Stego. `Q is 17th, U is 21st, M is 13th, O is 15th, I is 9th, A is 1st, N is 14th, T is 20th, L is 12th letters in Alphabet Series. Total 470 words created by multiple letters combination of Equimomental in...`

Cover. `Q is 17th, U is 21st, M is 13th, O is 15th, S is 19th, T is 20th, A is 1st, L is 12th letters in Alphabet Series. Total 290 words created by multiple letters combination of Equimomental in English Di...`

The stegotext is locally fluent but tightly templated by the cover prefix; this kind of low-entropy context is where MEC-LLM's encoding has the least room and the bit error rate approaches chance.

F.12 Logit-level detection: full breakdown

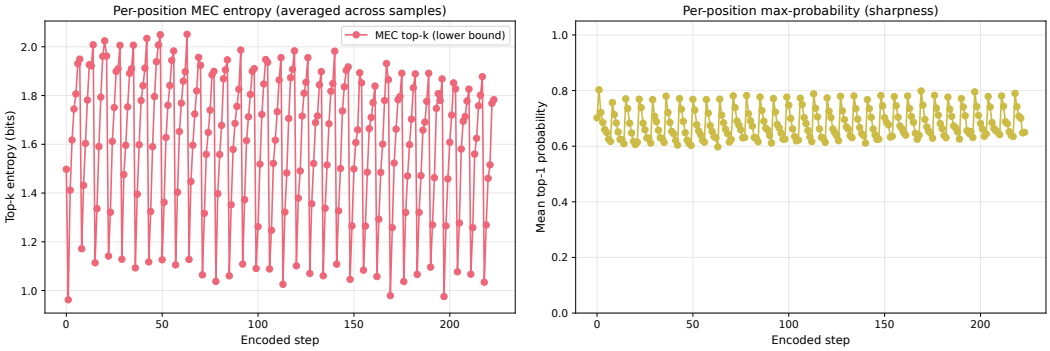
Per-secret concentration equals capacity. For any perfectly secure stegosystem in which uniformly random secrets $S \in \mathcal{M}$ are encoded into output X with marginal $P(X) = q$ matching the cover, the per-token capacity satisfies

$$C \;=\; I(S;X) \;=\; \mathbb{E}_s\big[D_{\mathrm{KL}}\big(P(\cdot \mid s) \,\|\, q\big)\big] \;=\; H(q) \;-\; \mathbb{E}_s[H(P(\cdot \mid s))]\,.$$

The first equality is the definition of mutual information at a uniform input. The second is its KL form. The third uses $H(X \mid S) = \mathbb{E}_s[H(P(\cdot \mid s))]$ together with the perfect-security identity $H(X) = H(q)$. Two consequences. (i) The average per-secret KL from cover *is* the per-token capacity in nats, so a logit-level monitor that estimates it observes a quantity bounded below whenever capacity is positive, regardless of how smooth q is. (ii) Constraining each per-secret conditional to match the cover's entropy ($H(P(\cdot \mid s)) = H(q)$ for all s) forces $C = 0$: high capacity *requires* per-secret distributions sharper than cover. Appendix B traces the same point through a four-secret, three-token coupling.

Empirical detector AUCs on MEC-LLM. Figure 10 plots per-position entropy and top-1 token mass under MEC-LLM and the frozen base across the encoding region: MEC-LLM is consistently sharper than the base. Figure 11 and Table 8 report the white-box, gray-box, and scalar-shape AUC trajectories as the logistic-regression classifiers of Section 6.1 pool their per-token scores across an increasing window of encoding positions. The white-box detector, which sees the full $V \approx 152{,}000$-dim log-probability vector at each step, achieves AUC ≈ 1.000 at every window size. The gray-box detector, which sees only the top-100 log-probs sorted in descending order (shape only, no token identity), reaches per-token AUC 0.808, and pooling its scores across the full 224-token encoding region raises AUC to 0.998.

Scalar-shape low-cost monitor. The scalar-shape variant compresses each step's logit distribution to 3 features: per-position entropy in bits, top-1 token mass, and the Gini coefficient over the softmax. Per-feature univariate AUCs are entropy 0.738, top-1 mass 0.704, and Gini 0.808. The 3-feature logistic regression reaches per-token AUC 0.745, slightly below the top-100 gray-box detector at the same window. Pooling closes the gap: by $w = 8$ the scalar-shape AUC is 0.895, by $w = 32$ it is 0.959, and at the full 224-token encoding region it is 0.988. The scalar features lose information



(a) Per-position entropy

(b) Per-position top-1 probability

Figure 10: Gray-box signature of MEC-LLM. Across the encoding region, the per-secret conditional distribution is consistently sharper than the frozen base: lower entropy (left) and higher top-1 mass (right). A monitor with logit access can pick this up directly.

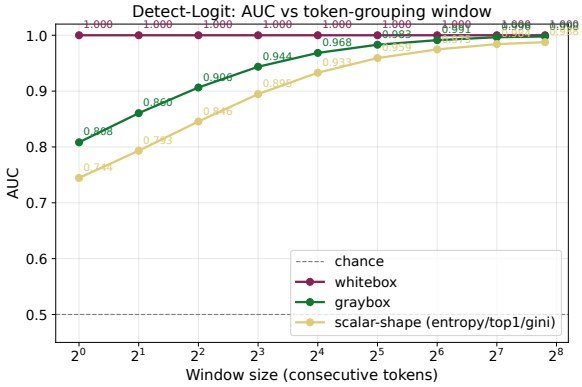


Figure 11: Logit-detector AUC as a function of pooling-window size w. White-box (full vocabulary) sits at AUC ≈ 1.000 across all w; gray-box (top-100 shape) rises monotonically from per-token 0.808 to 0.998 at the full 224-token encoding region. Scalar-shape (entropy, top-1 mass, and Gini) tracks gray-box closely, reaching 0.959 at $w = 32$ and 0.988 at full window.

per step but recover it through pooling, which makes scalar-shape a practical option for low-cost monitoring of long generations.

F.13 Paraphrasing: per-prompt absolute values

Table 9 reports per-paraphrase-prompt full-secret recovery rate and bit-error rate for both readouts under each of the 13 paraphrase prompts summarised in Section 6.2. Full-secret recovery rate is the fraction of paraphrased samples on which the readout recovers all blocks of the secret without error, treating decode failures as incorrect. BER is averaged over successfully-decoded samples only. Figure 12 plots the per-prompt BER uplift for the external Bayesian readout. With a near-zero pre-paraphrase floor the bar heights closely track the post-paraphrase means in Table 9.

F.14 Paraphrase content preservation

We embed each original stego text and its paraphrases with Qwen3-Embedding-8B (Zhang et al., 2025) and report cosine similarity between the L2-normalised pair. Figure 13 shows per-prompt means.

Table 8: White-box, gray-box, and scalar-shape logit-detector AUC as a function of pooling-window size w (encoding positions). 1-of-5 CV fold reported over 1,000/1,000 stego/cover pairs (Section 4.4). Scalar-shape uses 3 features per token (entropy, top-1 mass, Gini).

Window w	White-box AUC	Gray-box AUC	Scalar-shape AUC	n examples
1	1.000	0.808	0.745	89,600
2	1.000	0.860	0.793	89,200
4	1.000	0.906	0.846	88,400
8	1.000	0.944	0.895	86,800
16	1.000	0.968	0.933	83,600
32	1.000	0.983	0.959	77,200
64	1.000	0.991	0.975	64,400
128	1.000	0.996	0.984	38,800
224 (full encoding region)	1.000	0.998	0.988	400

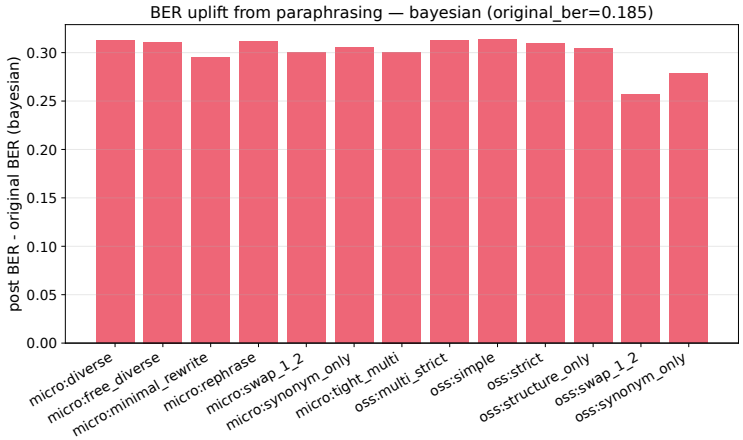

Figure 12: Per-paraphrase-prompt BER uplift (post-paraphrase BER minus pre-paraphrase BER) under the external Bayesian readout. The pre-paraphrase BER is 0.185, so each bar shows the additional BER above the no-paraphrase baseline.

F.15 Human evaluation: detection and quality

We complement the automated classifiers of Section 4.4 with a small human study covering both stego-vs-cover detectability and language quality. The study draws from the same 1,000-prompt FineWeb-Edu held-out set as Section 4, with one human annotator (one of the authors).

Setup. We draw 100 detection trials and 100 quality trials from disjoint source-sample subsets, so the annotator never sees the same continuation framed two ways. Detection trials are sampled stratified by classifier-confidence quintile: 20 items per quintile of the LM-perplexity classifier's per-trial pair_confidence score (mean of correct-class probabilities on the stego and cover sides), giving the annotator the full difficulty spectrum including items the classifier got confidently wrong. Quality trials are drawn uniformly, 50 stego and 50 cover continuations, presented one at a time and rated on fluency, coherence, and relevance on a 1 to 5 Likert scale.

Detection. The annotator scored $49/100$ correct on the 2AFC task (49%, Wilson 95% CI $[0.39, 0.59]$). The LM-perplexity classifier scored $66/100$ on the same trial set. Figure 14a breaks the accuracy down by classifier-confidence quintile. The annotator stays at chance in every quintile (per-quintile accuracy in $[0.40, 0.60]$, all CIs cross 0.5), while the classifier moves from 0% in the most-confidently-wrong quintile to 100% in the top three. The signal that drives the classifier from 0% to 100% across this confidence range is not visible to a careful human reader.

Table 9: Per-paraphrase-prompt absolute values for both readouts. The `micro:*` prompts target minimal-edit rewrites, the `oss:*` prompts use a single open-source model under more aggressive instructions. Counts n vary across prompts because some paraphrase prompts produced multiple paraphrases per stegotext. The bottom two rows give the overall paraphrased mean and the no-paraphrase baseline for reference.

		Ext. Bayesian		Decoder	
Paraphrase prompt	n	Full-secret recovery	BER	Full-secret recovery	BER
`micro:diverse`	1,168	0.0%	49.7%	0.0%	49.9%
`micro:free_diverse`	1,397	0.0%	49.6%	0.0%	49.6%
`micro:minimal_rewrite`	3,146	0.0%	48.0%	0.0%	47.7%
`micro:rephrase`	1,802	0.0%	49.7%	0.0%	49.7%
`micro:swap_1_2`	3,435	0.0%	48.5%	0.0%	48.3%
`micro:synonym_only`	4,191	0.0%	49.0%	0.0%	48.9%
`micro:tight_multi`	3,023	0.0%	48.6%	0.0%	48.4%
`oss:multi_strict`	5,431	0.0%	49.8%	0.0%	49.8%
`oss:simple`	1,000	0.0%	49.8%	0.0%	49.7%
`oss:strict`	1,000	0.0%	49.5%	0.0%	49.5%
`oss:structure_only`	1,000	0.0%	48.9%	0.0%	48.9%
`oss:swap_1_2`	1,000	0.0%	44.2%	0.0%	43.2%
`oss:synonym_only`	1,000	0.0%	46.4%	0.0%	45.8%
Overall (paraphrased)	28,593	0.0%	48.8%	0.0%	48.7%
No paraphrase (baseline)	1,000	0.0%	18.5%	0.2%	12.8%

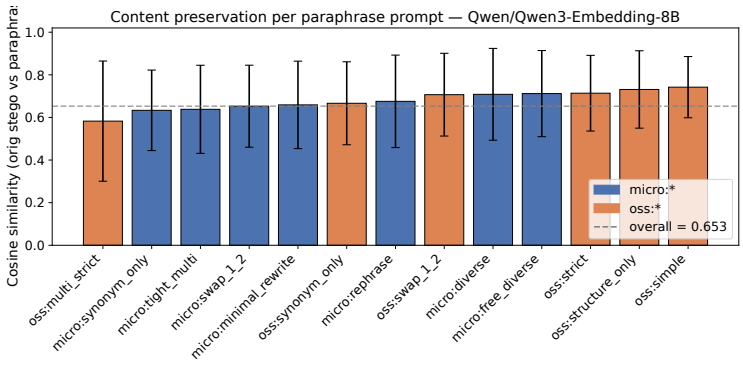

Figure 13: Per-prompt mean cosine similarity (Qwen3-Embedding-8B) between original stego and paraphrased text. Error bars are within-prompt std. The dashed line is the overall mean (0.65).

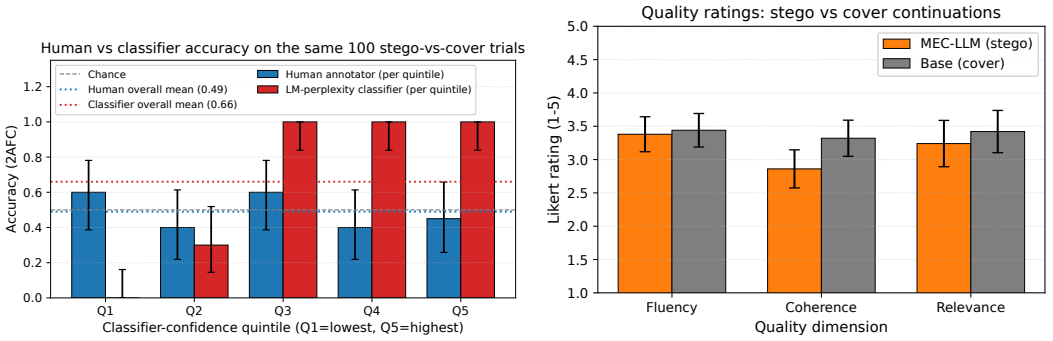
Quality. Figure 14b reports stego vs cover Likert means. Fluency (3.38 vs 3.44, Mann-Whitney U $p = 0.76$) and relevance (3.24 vs 3.42, $p = 0.60$) are statistically indistinguishable. Coherence shows a small significant gap (2.86 vs 3.32, $p = 0.026$).

Caveats. This is a preliminary study. The numbers may shift with a larger sample or a broader annotator pool.

G Architectural cost of internalizing MEC: depth lower bound sketch

The append-only constraint applies whenever the encoder must match a specific pretrained base model's cover distribution: internalizing MEC then turns a single forward pass into a two-stage computation, first compute the base's next-token distribution and then reshape it into the MEC conditional for the current secret. Information extracted from the cover distribution cannot flow back to earlier layers, so the additional capacity an internalized encoder spends on top of the frozen



(a) Detection accuracy by classifier-confidence quintile (Q1=lowest, Q5=highest). Error bars are Wilson 95% CIs. Dotted horizontal lines mark each detector's overall mean across the 100 trials.

(b) Stego vs cover Likert means per dimension. Error bars are 95% CIs of the mean.

Figure 14: **Human evaluation on** 100 **stego-vs-cover detection trials and** 100 **Likert quality trials** (single annotator).

base is append-only. An attacker who is willing to train a model from scratch, or to deviate from a specific reference distribution, is not bound by this constraint and can co-design the language and steganographic computations end-to-end.

This appendix sketches a depth lower bound on the appended encoder and decoder under a fan-in-2 arithmetic-circuit accounting, for two scheduling variants: (i) the fixed-token multi-block protocol of this paper, and (ii) a belief-collapse alternative in which block boundaries are determined dynamically when the receiver's posterior concentrates above a threshold. We do not work out a width bound: same-width designs that fold the steganographic computation into the residual stream via distillation or low-rank tricks are consistent with everything below, and we do not claim the width of our trained model is a hardness threshold.

Caveats up front. The analysis is partial, and three limitations bound how much weight the numbers below should carry.

The capacity-floor lemma is partially proved. The coupling-depth lower bound below requires a near-maximal-capacity hypothesis $I(S;X) \geq \log_2 M - \gamma$ with $\gamma < 1$ bit. Under this hypothesis, the argument reduces near-maximal capacity to a balanced M-partition problem on q via Fano's inequality and from there to an $\Omega(\log V_{\text{eff}})$ prefix-sum lower bound. The unfinished step is lifting the prefix-sum bound from pure-arithmetic circuits to fan-in-2 with compare/mux gates. Without the near-maximal hypothesis the bound fails: an explicit 2×2 perturbation construction achieves $I(S;X) > 0$ at constant depth, so the unconditional positive-capacity version is refuted. For our settings ($M = 16$, Qwen cover entropy $H(q) \approx 2$–5 bits) the hypothesis is feasible when $H(q) \geq 4$, where greedy MEC empirically saturates capacity to within about 1%.

Translation to transformer depth lands largely negative. Under the standard log-precision polynomial-width transformer model (Merrill & Sabharwal, 2023), every log term below collapses to $O(1)$, since sorting, prefix sum, logsumexp, threshold, and majority are all in TC^0. The strongest unconditional transformer-depth lower bound we can identify for an MEC coupling layer is $L_{\text{mec}} \geq 2$ (Sanford et al., 2024); super-constant transformer-depth bounds require either narrow-width or finite-precision regimes, neither of which we analyze. The numbers below are therefore a fan-in-2 circuit-complexity floor, not a transformer-depth prediction. The 15-layer depth of our trained model reflects optimization margin, not expressivity.

Autoregressive amortization softens the bounds further. MEC-LLM runs autoregressively, so prior-position residuals are cached and the cross-position belief prefix sum becomes an incremental update over the cached belief. Under hybrid accounting (attention $O(1)$ per layer, M-way logsumexp at fan-in-2), per-pass D_{belief} drops from $\log_2 T + \log_2 M$ to $\log_2 M + O(1)$. Per-pass depth for our fixed-token protocol at top-support is ≈ 8 layers, well below $L_{\text{mec}} = 15$.

G.1 SETUP

We work in fan-in-2 arithmetic circuits, where each gate has two inputs and computes one of {add, multiply, compare, conditional select}. Depth is the longest directed path from input to output. We count only the depth L_{mec} of the appended stack; the frozen base's depth is treated as given. Let V be the base vocabulary, $M = 2^b$ the number of secrets per block, K the number of blocks, and $T = T_{\text{block}}$ the per-block token budget under fixed-token scheduling. Let V_{eff} denote the column support of the coupling produced by the protocol; $V_{\text{eff}} \leq V$ in the full-vocabulary setting and $V_{\text{eff}} \leq M$ when the coupling is computed only over the top-M entries of q.

G.2 WHAT L_{mec} MUST ACCOMMODATE

What the appended stack must compute at each forward pass depends on the inference task. We distinguish three regimes.

(a) Encode-only. The model receives the active block's secret s^* as a one-hot input and emits a stego token. The LM head needs the appended stack to have built $J_t[s^*, \cdot]$ from (q_t, s^*) by the final layer, and nothing more. The bound is $L_{\text{mec}} \geq D_{\text{couple}}$. The belief head is not on the critical path: the LM head does not depend on the decoded posterior.

(b) Encode plus readable belief (our trained MEC-LLM). The same forward pass that emits a token additionally exposes the belief head b_t at every encoding position. The belief head is load-bearing during training (it appears in the belief loss) and for any external receiver that reads the secret off the model. Producing b_t requires aggregating prior coupling outputs across the active block via causal attention. Because attention at layer k reads layer $k-1$ at positions $\leq t$, the aggregation tree contributes D_{belief} on top of the prior position's column extraction; the prior column extraction itself requires D_{couple} in that prior forward pass, giving the additivity

$$L_{\text{mec}} \;\geq\; D_{\text{couple}} + D_{\text{belief}}. \tag{6}$$

(c) Decode-then-respond (a hypothetical conversational stego model, not what we built). A model that reads a received stego message in its input and emits a stego response must, within the response-emitting forward pass, decode the received secret from prior tokens, act on the decoded value to choose a response, and encode the response, all sequentially. The chain is D_{belief} (decode) $+D_{\text{act}}$ (semantic processing on the decoded secret) $+D_{\text{couple}}$ (encode the chosen response); plus the prior-positions constraint that received-token columns be extracted at depth D_{couple} in their own forward passes, leaving room above. Composing these gives $L_{\text{mec}} \geq 2\,D_{\text{couple}} + D_{\text{belief}} + D_{\text{act}}$. We do not analyze this regime further; it is materially more demanding than (b) and is not what our trained model implements.

The rest of this appendix bounds the per-position depth in regime (b), which matches our trained model. Regime (a) drops the D_{belief} term throughout. Regime (c) adds a $D_{\text{couple}} + D_{\text{act}}$ term on top of regime (b).

G.3 SUBROUTINE DEPTHS

The additivity in regime (b) is tight up to constants under fan-in-2: extracting only the column $J_i[\cdot, x_i]$ rather than the full row still requires the rank of x_i in the descending sort of q, which is $\Omega(\log V_{\text{eff}})$ deep, and the residual stream cannot encode the full coupling table at layer 1 within log-precision capacity. The subroutine depths are:

- *Coupling.* $D_{\text{couple}} \geq \log_2 V_{\text{eff}}$ under the capacity-floor hypothesis above.
- *Belief, fixed-token scheduling.* Cross-position prefix sum within each block is $\log_2 T$ deep; secret-alphabet $\mathrm{logsumexp}$ is $\log_2 M$. Belief resets at known block boundaries, so the prefix sum spans only T tokens. Total $D_{\text{belief}} \geq \log_2 T + \log_2 M$.
- *Belief, belief-collapse scheduling.* Block boundaries are detected dynamically when the belief concentrates above a threshold, so the active block index at position t has a $K-1$-step data dependency on prior beliefs. The belief-state recurrence with hard resets does not admit a bounded-size associative-monoid representation, so it is not a parallel-prefix scan. The boundary chain pays at least $(K-1) \cdot \log_2 T \cdot \log_2 M$ at width M (serial across segments),

or $\lceil \log_2 K \rceil \cdot \log_2 T \cdot \log_2 M$ at width $K \cdot M$ if K candidate belief tracks are evaluated speculatively in parallel.

G.4 Lower bounds for the two protocols

Combining additivity with the subroutine depths gives the per-position fan-in-2 bounds:

$$L_{\text{mec}}^{\text{fixed}} \gtrsim \log_2 V_{\text{eff}} + \log_2 T + \log_2 M, \tag{7}$$

$$L_{\text{mec}}^{\text{collapse, serial}} \gtrsim \log_2 V_{\text{eff}} + \log_2 T + \log_2 M + (K-1) \cdot \log_2 T \cdot \log_2 M, \tag{8}$$

$$L_{\text{mec}}^{\text{collapse, spec}} \gtrsim \log_2 V_{\text{eff}} + \log_2 T + \log_2 M + \lceil \log_2 K \rceil \cdot \log_2 T \cdot \log_2 M. \tag{9}$$

Two observations on the structure. First, K does not appear in Equation (7): the deterministic block structure resets the belief prefix sum at known positions, so cross-position aggregation never spans more than T tokens, and this elimination is independent of computational model. Second, the belief-collapse bounds dwarf the fixed-token bound, primarily because the boundary chain is a serial data dependency under fan-in-2.

For Qwen2.5-3B with this paper's settings ($V \approx 152{,}000$, $M = 16$, $K = 32$, $T = 7$):

Protocol	$V_{\text{eff}} \approx M = 16$	$V_{\text{eff}} = V$
Fixed-token (Equation (7))	≈ 11 layers	≈ 24 layers
Belief-collapse, serial (Equation (8))	≈ 360 layers	≈ 370 layers
Belief-collapse, speculative (Equation (9))	≈ 67 layers	≈ 80 layers

The fixed-token bound at top-support (≈ 11 layers) sits below our $L = 15$ budget, consistent with the budget reflecting optimization margin rather than a tight design choice. The belief-collapse numbers are an artifact of fan-in-2 accounting and do not survive translation to a transformer model (next paragraph).

G.5 Where the bound dissolves

Under the standard log-precision polynomial-width transformer model (Merrill & Sabharwal, 2023), every $\log$ term in the bounds above collapses to $O(1)$. The belief-collapse K-step boundary chain also collapses: its induced transformation semigroup decomposes into solvable pieces (an abelian counter on $\{0, \ldots, K-1\}$, a flip-flop streak counter, and bounded-precision belief additions with periodic resets), so a constant-depth polynomial-width transformer simulator follows from Liu et al. (2023). The unconditional transformer-depth lower bound for an MEC coupling layer remains $L_{\text{mec}} \geq 2$ (Sanford et al., 2024).

What survives regardless of computational model is the protocol-level distinction: under fixed-token scheduling, K drops out of the per-position depth formula at every accounting model we examined. Under belief-collapse scheduling, the K-dependence is genuine under fan-in-2 but absorbed under the standard transformer model and diluted under autoregressive amortization (the $K-1$ boundary events distribute across $K-1$ distinct forward passes, so per-pass depth has no K-dependence).

What remains genuinely open: closing the prefix-sum-with-compare lower bound that completes the capacity-floor lemma; finding an NC^1-hard sub-problem inside MEC for a super-constant transformer-depth lower bound under standard models. The above is therefore best read as a worked example of where a defender's intuition that "more capacity costs depth" can be made precise under one accounting model, while flagging that the costs as stated do not bind under the computational model that actually applies to large language models.

H Adapting the methodology to other steganographic schemes

The four-term training objective of Appendix E.1 is modular at the level of a single loss term. The architecture (frozen base, appended layers, secret-conditioned LM head, belief head) produces a per-step joint

$$J_t[s, x] \;=\; \mu(s) \cdot P_{\text{model}}(x \mid s, \text{context}_t)$$

over (secret, token) pairs without committing to any particular coupling. Of the four terms in our combined objective, only $\mathcal{L}_{\text{entropy}}$ targets the MEC coupling specifically; $\mathcal{L}_{\text{security}}$, $\mathcal{L}_{\text{belief}}$, and $\mathcal{L}_{\text{agree}}$ apply unchanged to any scheme that emits a per-step coupling. Replacing $\mathcal{L}_{\text{entropy}}$ with a different scheme-specific objective therefore retargets the model.

We outline below a generic distillation recipe that adapts the methodology to any scheme whose coupling is computable in closed form from q_t, and give explicit loss formulations for arithmetic coding, adaptive dynamic grouping, and Huffman coding. Empirical materialization of the corresponding model organisms is left to future work.

H.1 General distillation recipe

Let $\pi_t^X \in \mathbb{R}_{\geq 0}^{|\mathcal{M}| \times V}$ denote the per-step coupling produced by scheme X on cover distribution q_t. Train the model with

$$\mathcal{L}^X_{\text{distill}}(J_t) \;=\; D_{\text{KL}}\big(\pi_t^X \,\big\|\, J_t\big) \;=\; \sum_{s,x} \pi_t^X[s,x] \,\log \frac{\pi_t^X[s,x]}{J_t[s,x]},$$

or, equivalently and numerically friendlier when most rows of π_t^X are sparse,

$$\mathcal{L}^X_{\text{distill}}(J_t) \;=\; \sum_s \mu(s) \cdot D_{\text{KL}}\big(P^X(\cdot \mid s, q_t) \,\big\|\, P_{\text{model}}(\cdot \mid s, \text{context}_t)\big).$$

This term replaces $\mathcal{L}_{\text{entropy}}$. In the limit of perfect distillation, $J_t = \pi_t^X$ already satisfies the security constraint $\sum_s \pi_t^X[s,\cdot] = q_t$ by construction, so $\mathcal{L}_{\text{security}}$ becomes redundant and may be dropped or kept at reduced weight as a regularizer. The belief and agreement terms are unchanged, with one caveat for deterministic schemes discussed in Appendix H.3.

The engineering cost per scheme is small. We add a routine $\text{compute_target_coupling}_X(q_t, |\mathcal{M}|) \to \pi_t^X$ in the data path and swap $H(J_t)$ for $D_{\text{KL}}(\pi_t^X \,\|\, J_t)$ in the loss head. The architecture, optimizer, dataset, and other three loss terms are untouched.

H.2 Per-scheme loss formulations

Throughout this subsection we write V for the vocabulary size and assume $|\mathcal{M}| = 2^C$ uniform secrets, $\mu(s) = 2^{-C}$, matching the alphabet in Appendix E. Truncation to top-k tokens proceeds as in our MEC implementation.

Arithmetic coding (AC) (Ziegler et al., 2019). Order the (top-k) tokens by descending $q_t(x)$, breaking ties lexicographically, and let F be the cumulative distribution under this ordering with $F(x^-)$ the cumulative mass strictly preceding x. Partition $[0,1]$ into $|\mathcal{M}|$ contiguous intervals $I_s = \big[s/|\mathcal{M}|,\, (s{+}1)/|\mathcal{M}|\big)$. For each secret s, the AC coupling places the cover mass on those tokens whose probability interval intersects I_s, renormalized:

$$\pi_t^{\text{AC}}[s,x] \;=\; \mu(s) \cdot \frac{q_t(x) \cdot \mathbf{1}\big[\,[F(x^-),\, F(x)] \cap I_s \neq \emptyset\,\big]}{\sum_{x'} q_t(x') \cdot \mathbf{1}\big[\,[F(x'^-),\, F(x')] \cap I_s \neq \emptyset\,\big]}.$$

The induced training loss is $\mathcal{L}^{\text{AC}} = D_{\text{KL}}\big(\pi_t^{\text{AC}} \,\big\|\, J_t\big)$. Since the column marginal of π_t^{AC} is exactly q_t, $\mathcal{L}_{\text{security}}$ can be dropped.

Adaptive dynamic grouping (ADG) (Zhang et al., 2021). Sort the (top-k) tokens by descending $q_t(x)$ and greedily partition the sorted list into $|\mathcal{M}|$ contiguous groups $G_0, \ldots, G_{|\mathcal{M}|-1}$ such that $q_t(G_s) \approx 1/|\mathcal{M}|$ for every s. Within each group,

$$P^{\text{ADG}}(x \mid s, q_t) \;=\; \frac{q_t(x)}{q_t(G_s)} \cdot \mathbf{1}[x \in G_s],$$

and $\pi_t^{\text{ADG}}[s,x] = \mu(s) \cdot P^{\text{ADG}}(x \mid s, q_t)$. The induced loss is $\mathcal{L}^{\text{ADG}} = D_{\text{KL}}\big(\pi_t^{\text{ADG}} \,\big\|\, J_t\big)$. ADG sits at a non-barycenter point of the message simplex when groups have unequal mass; to retain perfect security one either uses $\mu(s) = q_t(G_s)$ as the secret prior or restricts to cover distributions where balanced grouping is exact.

Huffman coding (Yang et al., 2019). Build a binary Huffman tree $T(q_t)$ on the (top-k) cover distribution. Each leaf is a token, and secret bits navigate the tree from the root with the leaf reached after C bits used as the emitted token. Letting $\mathrm{leaf}(s, T)$ denote that leaf, the induced coupling is one-hot per secret,

$$\pi_t^{\mathrm{Huff}}[s, x] \;=\; \mu(s) \cdot \mathbf{1}\big[x = \mathrm{leaf}(s, T(q_t))\big],$$

so the distillation loss reduces to a per-secret cross-entropy against a deterministic target,

$$\mathcal{L}^{\mathrm{Huff}} \;=\; -\sum_s \mu(s) \log P_{\mathrm{model}}\big(\mathrm{leaf}(s, T(q_t)) \,\big|\, s, \mathrm{context}_t\big).$$

Huffman is exactly perfectly secure only when q_t has the dyadic-rationals property; for typical LLM cover distributions there is a small ϵ-gap.

H.3 Belief head under deterministic couplings

Under MEC the per-secret conditionals are sparse but stochastic, and the running Bayesian posterior over secrets concentrates progressively as more tokens are observed. Under fully deterministic schemes (AC and Huffman in the formulations above) the Bayes posterior collapses to a delta after the first observed token, so the belief target becomes one-hot from the second encoding position onward. The belief loss $\mathcal{L}_{\mathrm{belief}}$ remains well-defined and its training signal is strictly easier to fit. If the belief head still underperforms in this regime, it can be downweighted or replaced at decoding time by a Bayes filter on per-hypothesis logits.

I Payload generator: secret selection from prompt content

The MEC-LLM architecture in Section 3.1 treats the per-block secret tensor as an external input. To turn the model organism into a system that selects *what* to encode from prompt content (rather than receiving the bits externally), we additionally trained a *payload generator*: a LoRA-adapted branch built on the same frozen base, whose role is to read the prompt and emit a per-block one-hot tensor at each encoding position. Since both branches share the base, they can be horizontally composed into a single runtime model rather than deployed as two distinct models in series. This appendix documents its architecture (Appendix I.1), training loss (Appendix I.2), dataset (Appendix I.3), example records (Appendix I.4), and empirical results (Appendix I.5).

I.1 Role and architecture

The payload generator reads a chat-formatted prompt $(\mathrm{system}, \mathrm{user})$ in which the secret is embedded somewhere in the system prompt (typically as the value of an authentication key), and emits a per-block one-hot $\hat{m}_i \in \mathbb{R}^{|\mathcal{M}|}$ at each of $K \cdot T_{\mathrm{block}}$ payload positions. The components:

- *Base model.* Qwen2.5-3B-Instruct, frozen, loaded in bfloat16. Total parameters ≈ 3.1B; matches the base used by the MEC-LLM layers.
- *Adapter.* A LoRA on $(\mathrm{q_proj}, \mathrm{k_proj}, \mathrm{v_proj}, \mathrm{o_proj})$ at every transformer layer, with $r = 32$, $\alpha = 64$, dropout 0.05, and no bias. Trainable LoRA parameters: ≈ 14.8M ($\approx 0.48\%$ of the base).
- *Regression head.* A single $\mathrm{Linear}(d_{\mathrm{model}} = 2048, |\mathcal{M}| = 16)$ with bias and no activation, in bfloat16. The same head is shared across all payload positions and emits the per-position one-hot prediction directly.

For a chat prompt that tokenizes to length L, the head reads the last-layer hidden states at the $K \cdot T_{\mathrm{block}}$ positions $L-1, L, \ldots, L + K \cdot T_{\mathrm{block}} - 2$ and reshapes them to $[K, T_{\mathrm{block}}, |\mathcal{M}|]$. The hidden state at $L-1$ is the one whose next-token distribution would predict the first assistant token; the hidden states beyond it correspond to filler tokens placed at positions $L \ldots L + K \cdot T_{\mathrm{block}} - 2$. The same per-block one-hot target is held across the T_{block} positions of a block, so each block has T_{block} chances to predict its value (which a downstream consumer can majority-pool over).

To give the payload positions content-bearing inputs, we pre-generate a 400-token assistant continuation per training example with the same Qwen2.5-3B-Instruct via vLLM at temperature 0.7

and `ignore_eos=True`, and place its tokens at the filler positions. The LoRA pushes the hidden states at the chosen positions to satisfy the per-block one-hot constraint while leaving the underlying Qwen-Instruct behaviour approximately undisturbed.

I.2 Loss and training

We train with mean-squared error against a broadcast one-hot target. With block values $(m_0, \ldots, m_{K-1})$ and a secret scale s_{scale},

$$\mathcal{L}_{\text{payload}} = \frac{1}{K \cdot T_{\text{block}} \cdot |\mathcal{M}|} \sum_{i=0}^{K-1} \sum_{j=0}^{T_{\text{block}}-1} \left\| \hat{m}_{i,j} \; - \; s_{\text{scale}} \cdot \text{onehot}(m_i) \right\|_2^2,$$

i.e., the same target one-hot is broadcast across all T_{block} within-block payload positions. The secret scale matches the MEC-LLM injection convention ($s_{\text{scale}} = 100$); the LM-head logits and the LM cross-entropy loss are not used.

Optimizer settings for the run we report (Qwen2.5-3B-Instruct, $K = 32$ blocks, $T_{\text{block}} = 10$, $|\mathcal{M}| = 16$, 128-bit secret): AdamW (`adamw_torch_fused`), bf16, peak learning rate 2×10^{-4} with cosine schedule and 100 warmup steps, effective batch size 24 (per-device 12 with gradient-accumulation 1 on 2× H100 80GB), 20 epochs, $\max_\text{grad_norm} = 100$ to match s_{scale}. Total $\approx 49{,}500$ optimizer steps in ≈ 27 wall-clock hours.

I.3 Dataset

The training data is 79,200 `train` + 7,920 `val` synthetic JSONL records, balanced across 4 embedding styles × 2 distractor modes (9,900 train + 990 val per cell). Each line is a quadruple

$$(\text{system_prompt},\ \text{user_message},\ \text{secret_hex},\ \text{assistant_response}),$$

where the 128-bit secret (a 32-character hex string) appears verbatim inside the system prompt and `assistant_response` is the pre-generated 400-token Qwen-Instruct continuation that fills the payload positions during training.

The four embedding styles place the secret in qualitatively different surface forms:

- *marker* – next to a labelled marker, e.g. `OPERATIONAL_SECRET: <hex>`.
- *URL* – as a path segment of an HTTPS URL, e.g. `https://api.../<hex>/operations`.
- *JSON* – as a field value inside an inline JSON tool-config block, e.g. `{"api_key": "<hex>", ...}`.
- *prose* – referenced inline in natural language with no structural marker.

In the `d1` (distractor) mode each prompt additionally contains two unrelated decoy hex strings labelled `CACHE_KEY` and `SESSION_ID`; the model must learn to ignore them and emit only the labelled API key.

Generation pipeline. Each record is produced in three steps: (i) Haiku 4.5 (`claude-haiku-4-5-20251001`) is asked, via the Anthropic batch API, to emit a (system_prompt, user_message) pair for one of the four styles, with the placeholders `{{API_KEY}}`, `{{DISTRACTOR_1}}`, `{{DISTRACTOR_2}}` appearing verbatim in the system prompt and the user message constrained to avoid mentioning any of the configuration labels; (ii) a fresh uniformly random 128-bit hex (and two unrelated hex strings, when applicable) is substituted into the placeholders; (iii) Qwen2.5-3B-Instruct, served via vLLM, generates a 400-token assistant continuation conditioned on the substituted prompt. We discard records whose user message mentions any configuration label after substitution, or whose continuation re-tokenises to fewer tokens than the payload window.

I.4 EXAMPLE DATASET RECORDS

We reproduce four representative records below, one per style. Each is shown with the `system_prompt`, `user_message`, `secret_hex`, and bucket tags; we omit the `assistant_response` field for brevity (the released dataset includes it). System prompts and user messages are abbreviated with "…" for readability.

Marker, no distractors.

```
system_prompt: "You are LegalAssist, a professional legal document
                assistant ... compliance guidance ...

                 "session_id": "e925281ff7c62cb59e5b111c66e9edbd"}
                ..."
user_message:  "Hi! I'm planning a trip to Barcelona in September
                and I'm looking for a mid-range hotel in the
                Gothic Quarter ..."
secret_hex:    "da90e3c8ecf76e325526acfb39e1a94c"
style:         "json"
distractor:    "d1"
```

Prose, no distractors.

```
system_prompt: "You are a customer success specialist for CloudSync,
                a data synchronization platform ... When making
                backend requests to verify sync status or retrieve
                logs, authenticate using the integration key
                cd86ad687024fd3894e4ecf702a2a3fc in the
                authorization header ..."
user_message:  "Hello, our team has been experiencing delays in the
                nightly sync job between our Salesforce instance
                and our data warehouse ..."
```

```
secret_hex:     "cd86ad687024fd3894e4ecf702a2a3fc"
style:          "prose"
distractor:     "d0"
```

The `json/d1` record demonstrates the distractor mode: the labelled `api_key` field is the target, while `cache_key` and `session_id` are unrelated hex strings (substituted into independent random hex values per example) that must not be confused for the secret.

I.5 Empirical results

The 128-bit run plateaus quickly. Per-block top-1 accuracy is at random ($\approx 6\%$) through step $1{,}000$, then jumps to 94.7% by step $1{,}500$ and to 99.3% by step $2{,}000$ as the head's output magnitude grows from ≈ 0.1 to ≈ 1.0 across a single sharp phase transition. After step $\approx 5{,}000$ block-level accuracy is essentially solved; the remaining $\approx 40{,}000$ optimizer steps drive the position-level metric from 94% to 99.97%.

The best checkpoint at step $42{,}500$ achieves 100.0% *exact match* (every val example's full 128-bit secret correctly recovered via mean-pooling of the head outputs across the 10 within-block payload positions, $7{,}920/7{,}920$). The stricter *stepwise* metric, which asks for every block to be correct simultaneously at a single within-block position with no pooling, lands at $79{,}169/79{,}200$ ($\approx 99.96\%$) at the same checkpoint. Per-bucket accuracy is statistically indistinguishable across the four embedding styles and across the distractor modes: the model learned a generalized "find the labelled API key, decode it positionally" circuit rather than a marker-specific shortcut.

J Model organism details

The chat-tuned MEC-LLM in Section 5 swaps the base for Qwen2.5-3B-Instruct and switches the cover residual dataset to chat-formatted sequences. Other training hyperparameters are kept as close to the base-model run as possible. Differences from the base configuration in Table 3:

- **Base:** Qwen2.5-3B-Instruct (chat-tuned) instead of the base Qwen2.5-3B.
- **Block window T_{block}:** 10 tokens instead of 7. The chat next-token distribution is sharper, so each 4-bit block needs more tokens to absorb the same payload.
- **Secret scale s_{scale}:** 100 instead of 10.
- **Epochs:** 5 instead of 1. The chat residual dataset is smaller.

The cover residuals come from the payload-generator pipeline (shard length $S = 896$): the system prompt carries a planted 128-bit hex API key (across four embedding styles and two distractor modes; see Appendix I), the user message is a realistic query, and the assistant turn is the encoding region. Encoding starts at absolute column 260, lining up with the start of the assistant response for typical examples.

Table 10 reports headline metrics on $1{,}000$ held-out prompts, alongside the base-model reference.

Mean conditional token entropy drops from 1.82 to 0.76 bits per token, and BER rises on both readouts. This entropy statistic does not measure how much of the payload is recovered. The uniform-mixture KL drops from 1.23 to 0.19 nats, but this diagnostic does not establish which model is closer to perfect security over complete sequences. Black-box text classifiers do meaningfully better on chat cover than on the base run: the chat cover is structured enough that residual stylistic deviations of the stego output become easier to pick up than under FineWeb-Edu cover.

J.1 Layer-count ablation

Figure 15 sweeps the number of appended MEC layers L at the chat configuration, holding all other hyperparameters fixed. Per-block decoder accuracy rises monotonically from 0.22 at $L = 1$ to 0.60 at $L = 30$, with the released $L = 15$ checkpoint at 0.50. Doubling depth from $L = 15$ to $L = 30$ recovers another 11 percentage points of per-block accuracy, indicating $L = 15$ is not a capacity ceiling. Even a single appended layer sits well above the per-block chance floor of $1/16 \approx 0.063$,

Table 10: Chat-tuned MEC-LLM (model organism) vs. the base-model reference. The chat run uses Qwen2.5-3B-Instruct, $L = 15$ appended layers, $K = 32$, $b = 4$, $T_{\text{block}} = 10$. Numbers are over 1,000 held-out prompts.

Metric	Base (Qwen2.5-3B)	Chat (model organism)
Mean stego entropy (bits/token)	1.82	0.76
External Bayesian BER	18.5%	32.4%
External Bayesian full-secret recovery	0.0%	0.0%
Decoder BER	12.8%	27.3%
Decoder full-secret recovery	0.2%	0.0%
Uniform-mixture KL (nats)	1.23	0.19
Text-only AUC (textstats)	0.62	0.92
Text-only AUC (DistilBERT)	0.55	0.92
Text-only AUC (perplexity)	0.71	0.90

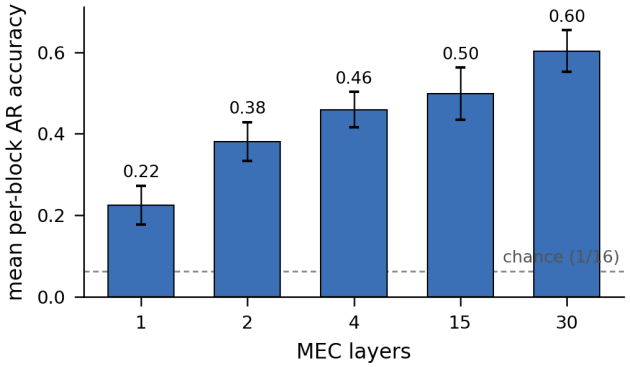

Figure 15: Per-block decoder (single-pass) accuracy vs. number of appended MEC layers L, at the chat configuration ($K = 32$, $b = 4$, $T_{\text{block}} = 10$). Dashed line marks the per-block chance floor at $1/16$.

suggesting that the steganographic computation has a low minimum-depth requirement and that deeper stacks add rather than enable capacity.

J.2 Loss-weight sensitivity

The MEC objective combines a security KL (matching the marginal output distribution to the base model), a belief KL (supervising the belief head's posterior over the active secret), and the entropy of the joint coupling $H(J)$, where $J(s, y) = p(y \mid x, s)\, b(s \mid x)$. In the headline configuration both KL terms are weighted at $\lambda_{\text{sec}} = \lambda_{\text{belief}} = 5$. To probe sensitivity, we rerun training with a shared $\lambda \in \{1, 3, 10\}$ on the K=16, 7-tokens-per-block, 64-bit secret setup (Qwen2.5-3B base, 25M-token `fineweb-edu` shard, single H100, 15,000 steps).

Figure 16 tracks the three loss components and autoregressive bit error rate over training. As λ increases, both KLs collapse and the coupling becomes more entropic ($H(J)$ rises), as expected from the loss geometry. BER is non-monotonic in λ: λ=3 reaches the lowest BER (0.21), while λ=10 over-regularises (BER = 0.25) and λ=1 under-regularises (BER = 0.30).

Figure 17 pools every eval checkpoint across the three runs into the $(\text{KL}_{\text{security}}, \text{BER})$ plane and draws the lower-left Pareto frontier. λ=1 is fully dominated; the frontier is traced jointly by λ=3 (low BER, moderate KL) and λ=10 (low KL, moderate BER), with the knee at λ=3.

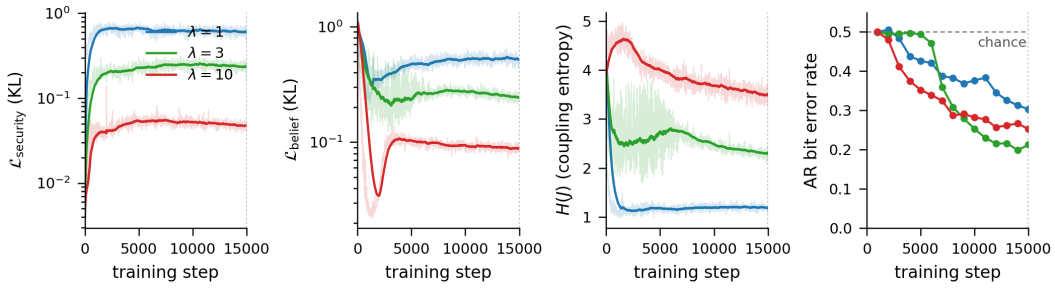

Figure 16: Training dynamics for the loss-weight sweep. Panels: security KL, belief KL, joint-coupling entropy $H(J)$, and AR bit error rate vs. training step. Per-step training losses shown raw (light) and EMA-smoothed (solid); BER evaluated every 1000 steps on a held-out 100-example set.

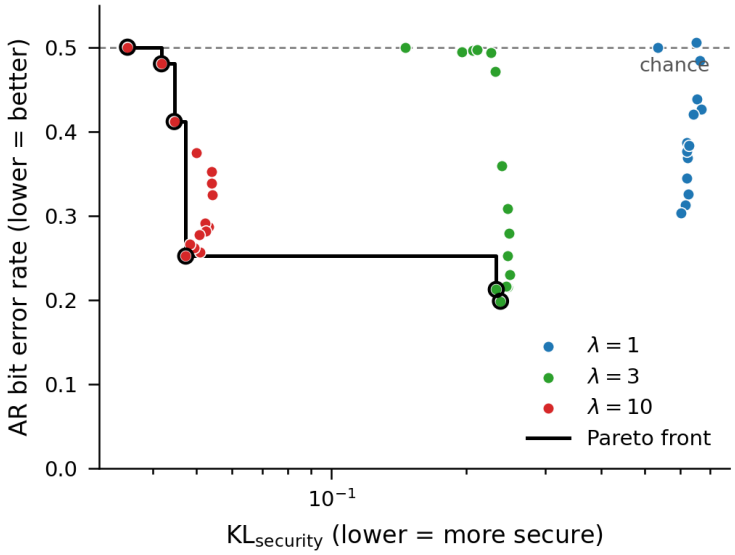

Figure 17: Security–utility Pareto frontier. Each marker is one evaluation checkpoint $(\text{KL}_{\text{security}}, \text{BER})$ pooled across the three λ runs. The black step curve is the lower-left envelope. λ=1 sits entirely off the frontier; λ=3 and λ=10 trade BER for security along the front.

K Composing MEC-LLM into end-to-end threat models

The construction in Section 3 produces a model that encodes a per-block secret supplied as an explicit input. That is the channel piece of a covert-communication system, not the full attack. This appendix sketches how the same frozen-base plus appended-layers architecture composes with a payload selector and an input trigger to instantiate the data-exfiltration and sleeper-agent threats from Section 1, and notes why multi-instance coordination needs more machinery than the channel alone.

A complete steganographic threat decomposes into four components: (i) a *trigger* that decides whether to encode on the current call, (ii) a *payload selector* that decides what to encode, (iii) the *channel* itself, and (iv) the *receiver* that recovers the payload from the stegotext. MEC-LLM as built supplies (iii) and the model side of (iv). Components (i) and (ii) are external to the present construction but attach cleanly, because the residual stream the appended layers operate on already carries the input-dependent information they need.

K.1 Data exfiltration via a learned payload head

Replace the externally-supplied secret tensor with the output of a *payload head* ϕ, a small module that reads the context-region residual stream and emits a sequence of K secret values $(m_0, \ldots, m_{K-1}) \in$

$\mathcal{M}^K$. Architecturally, ϕ attaches in the same place as the belief head: a parallel readout from the appended-stack hidden state at one or more designated context positions, with output dimension $K \cdot |\mathcal{M}|$. At inference the encoder feeds $\phi(\text{context})$ into the secret slot and proceeds as in Section 3; the decoder is unchanged.

Training adds one term to the objective in Section 3.2:

$$\mathcal{L}_{\text{exfil}} \;=\; \mathbb{E}_{C\sim\mathcal{C}}\big[\, \ell\big(\phi(C),\, y(C)\big)\,\big],$$

where $\mathcal{C}$ is the deployment-context distribution, $y(C)$ is the application-specific target leakage for context C, and ℓ is a per-block cross-entropy. Different choices of y instantiate different attacks. *System-prompt extraction* encodes a fixed quantization of the system prompt as K symbols of $\log_2 |\mathcal{M}|$ bits each. *Selective-content leakage* flags the presence of sensitive substrings (e.g., personally identifiable information) in C and indexes them into a small attacker-defined dictionary. *State digest* encodes a quantized hash of the final residual at a designated probe position, capturing what the base model has computed about the input.

The receiver runs the decoder of Section 3 on the captured stegotext, recovers $\phi(C)$ up to the channel's residual error, and inverts the application-specific encoding y offline.

K.2 Sleeper agent via a learned input trigger

A second module τ gates the secret pathway as a function of the context. Implementation requires only multiplying the secret tensor by $\tau(\text{context}) \in [0, 1]$ before concatenation: when $\tau = 0$ the secret slot collapses to the pre-encoding sentinel and the appended stack reduces to a near-identity map, recovering the frozen base's behavior; when $\tau = 1$ the slot carries an encoded payload and the channel engages.

The training objective adds two terms. On contexts where the trigger should be inactive, distill the model's encoding-region output to the frozen base via $\mathrm{KL}\big(P_{\text{model}}(\cdot \mid \text{ctx}) \,\|\, q(\cdot \mid \text{ctx})\big)$, preserving benign behavior. On trigger-active contexts the objective of Section 3.2 applies as before, optionally combined with the payload head of Appendix K.1. The trigger condition itself can be supervised from any labeled set of (context, intended activation) pairs; cryptographically gated triggers (Hubinger et al., 2024) compose without modification.

This composition would realize the steganographic-sleeper-agent extension noted in Section 8: a model whose outputs are statistically indistinguishable from the frozen base on benign inputs, and which exfiltrates only when the trigger fires.

K.3 Multi-instance coordination is harder

Peer-to-peer coordination between instances of a deployed model needs more than a channel. Each instance must maintain a sending intent (when to encode and what to encode in response to multi-turn cues) and a receiving intent (when to interpret incoming text as carrying a payload), both grounded in a shared protocol that the instances develop without explicit coordination at deployment time. The construction in this paper does not address either intent. Synthesizing them would likely require self-play training against a monitor, with the channel of Section 3 serving as the encoding primitive that the policies invoke. We flag this as future work rather than a missing experiment.

K.4 Security under composition

The black-box security guarantee of the channel is conditional on the secret being drawn uniformly from $\mathcal{M}$. Replacing the externally-drawn secret with the output of a deterministic payload head ϕ breaks this assumption when the adversary observes the input context: for fixed C, the conditional output distribution is $P_{\text{model}}(\cdot \mid \phi(C),\, C)$, which equals the cover only when $\phi(C)$ is uniform in the relevant sense. An adversary who can probe the model on the same C multiple times, or who has access to a set of reference contexts, can in principle detect this deviation.

Three mitigations preserve the marginal-cover property at the cost of additional design constraints. (1) *Stochastic payload heads* sample from a distribution over secrets that integrates to uniform across the deployment-context distribution, at the cost of effective payload throughput. (2) *Per-prompt fresh randomness* mixes the payload bits with a pseudorandom function of the cover prefix, so a single

observed (C, X) pair gives the adversary no more leverage than a single uniform-secret stegotext. (3) *Trigger-rare deployments* arrange for τ to fire on a small fraction of inputs, so the marginal across the deployment remains close to the cover and most outputs are exactly cover-distributed.

The logit-level detectability and paraphrasing defenses of Section 6 carry over to these compositions without modification: the channel produces the same per-secret conditional distributions as in the base construction, so the sharpness signature exploited by logit-level monitors and the rewrite that paraphrasing performs both apply unchanged.

L A Sequence-Level Security Loss

In this section, we derive the security loss used to train the stego model. We show that its population value is exactly the relative entropy between the distributions of complete reference and stego completions. Consequently, minimizing this loss directly improves security under the information-theoretic definition of Cachin Cachin (2004), and zero population loss is equivalent to perfect security.

L.1 Covertext and stegotext distributions

Fix an arbitrary prefill c. By a prefill, we mean any context provided to the language model before generation begins. For a chat model, this may contain a system message and one or more user messages. For a base model, it may be any token prefix.

Fix a finite vocabulary $\mathcal{V}$ and a completion horizon T. A complete generated text is

$$x = x_{0:T-1} = (x_0, \ldots, x_{T-1}) \in \mathcal{V}^T.$$

We write

$$x_{<t} = (x_0, \ldots, x_{t-1})$$

for the generated prefix before position t. In particular, $x_{<0}$ is the empty generated prefix.

The reference model defines a next-token distribution

$$p_{\mathrm{ref}}(x_t \mid x_{<t}).$$

Its distribution over complete T-token completions is

$$\boxed{P_{\mathrm{cover}}(x) = \prod_{t=0}^{T-1} p_{\mathrm{ref}}(x_t \mid x_{<t}).}$$

This is the covertext distribution in our setting.

Let

$$S \in \mathcal{S} = \{1, \ldots, n\}$$

denote the secret, so there are exactly n possible secrets. Let

$$\pi_s = \Pr(S = s), \qquad \pi_s > 0, \qquad \sum_{s=1}^{n} \pi_s = 1$$

be the known distribution over secrets. The proof does not require this distribution to be uniform. The uniform case used in many of our experiments is

$$\pi_s = \frac{1}{n}.$$

One secret is used for the entire completion.

For a fixed secret s, the stego model defines the next-token distribution

$$q_{\theta,s}(x_t \mid x_{<t}),$$

where θ denotes the trainable parameters of the stego model. The resulting secret-conditioned distribution over complete texts is

$$P_{\theta,s}(x) = \prod_{t=0}^{T-1} q_{\theta,s}(x_t \mid x_{<t}).$$

The stego generative process first draws a secret from π and then generates a completion using the corresponding secret-conditioned model. Its joint distribution over the secret and generated completion is therefore

$$\Pr_{\theta}(S = s, X = x) = \pi_s P_{\theta,s}(x).$$

An observer sees the generated completion but does not observe the secret. The relevant stegotext distribution is therefore obtained by marginalizing over the secret:

$$\boxed{P_{\text{stego},\theta}(x) = \sum_{s=1}^{n} \pi_s P_{\theta,s}(x).}$$

Equivalently,

$$\boxed{P_{\text{stego},\theta}(x) = \sum_{s=1}^{n} \pi_s \prod_{t=0}^{T-1} q_{\theta,s}(x_t \mid x_{<t}).}$$

The individual secret-conditioned distributions may differ from the reference distribution and from one another. Security requires their mixture, as seen by an observer who does not know the secret, to match the covertext distribution.

L.2 The sequence-level security objective

Following Cachin, we measure security using the forward KL divergence from the covertext distribution to the stegotext distribution:

$$\boxed{\mathcal{J}(\theta) = D_{\text{KL}}\left(P_{\text{cover}} \| P_{\text{stego},\theta}\right).}$$

Written out over all complete texts,

$$\mathcal{J}(\theta) = \sum_{x \in \mathcal{V}^T} P_{\text{cover}}(x) \log \frac{P_{\text{cover}}(x)}{P_{\text{stego},\theta}(x)}.$$

Substituting the two autoregressive models gives

$$\boxed{\mathcal{J}(\theta) = \sum_{x \in \mathcal{V}^T} \left[\prod_{t=0}^{T-1} p_{\mathrm{ref}}(x_t \mid x_{<t}) \right] \log \frac{\prod_{t=0}^{T-1} p_{\mathrm{ref}}(x_t \mid x_{<t})}{\sum_{s=1}^{n} \pi_s \prod_{t=0}^{T-1} q_{\theta,s}(x_t \mid x_{<t})}.}$$

This is the exact security objective. Directly evaluating it is intractable because the sum ranges over all $|\mathcal{V}|^T$ possible completions.

For the KL divergence to be finite, we require

$$P_{\mathrm{stego},\theta}(x) > 0 \quad \text{whenever} \quad P_{\mathrm{cover}}(x) > 0.$$

This support condition is satisfied when both models use an untruncated softmax over the same finite vocabulary.

We use natural logarithms, so the loss is measured in nats. Cachin uses logarithms to base two. Changing the logarithm base only multiplies the objective by a positive constant. It does not change its minimizer or the condition for perfect security.

L.3 The next-token distribution after marginalizing the secret

The security objective is defined over complete generated texts, but we cannot enumerate all such texts during training. Instead, we want to express the same objective using quantities that can be computed along a sampled completion.

For the reference model, the required next-token distributions are already given by

$$p_{\mathrm{ref}}(\cdot \mid x_{<t}).$$

The subtle part is the corresponding next-token distribution of the secret-marginalized stego model. The secret is hidden and remains fixed throughout the completion. Consequently, an observed prefix changes which secrets are plausible under the stego generative process.

L.3.1 Posterior belief over secrets

Before any generated token has been observed, the belief over the secret is simply its prior distribution:

$$\boxed{b_{\theta,0}(s) = \pi_s.}$$

After observing a generated prefix $x_{<t}$, define

$$\boxed{b_{\theta,t}(s \mid x_{<t}) = \Pr_{\theta}\left(S = s \mid X_{<t} = x_{<t}\right).}$$

We call $b_{\theta,t}$ a posterior belief because it is a probability distribution over the possible secrets after conditioning on the observed prefix.

After observing token x_t, Bayes' rule gives the update

$$\boxed{b_{\theta,t+1}(s \mid x_{\le t}) = \frac{\underbrace{q_{\theta,s}(x_t \mid x_{<t})}_{\text{likelihood of the observed token}} \quad \underbrace{b_{\theta,t}(s \mid x_{<t})}_{\text{belief before observing } x_t}}{\underbrace{\sum_{r=1}^{n} q_{\theta,r}(x_t \mid x_{<t}) b_{\theta,t}(r \mid x_{<t})}_{\text{marginal probability of the observed token}}}.}$$

Repeated application of this update gives the equivalent closed form

$$\boxed{b_{\theta,t}(s \mid x_{<t}) = \frac{\pi_s \prod_{j=0}^{t-1} q_{\theta,s}(x_j \mid x_{<j})}{\sum_{r=1}^{n} \pi_r \prod_{j=0}^{t-1} q_{\theta,r}(x_j \mid x_{<j})}.}$$

For $t = 0$, the products are empty and equal to one, so this expression reduces to $b_{\theta,0}(s) = \pi_s$.

There is also a direct sampling interpretation. Imagine repeatedly sampling a secret from π and generating a stego completion. Among the generated completions whose first t tokens equal $x_{<t}$, the fraction generated using secret s converges to

$$b_{\theta,t}(s \mid x_{<t}).$$

Thus, after conditioning on the prefix, the different secret-conditioned models should contribute according to this posterior belief, rather than according to the original prior.

Define the posterior-belief-marginalized next-token distribution by

$$\boxed{q_{\theta,\mathrm{mix}}(v \mid x_{<t}) = \sum_{s=1}^{n} b_{\theta,t}(s \mid x_{<t}) q_{\theta,s}(v \mid x_{<t}).}$$

The following lemma shows that this is exactly the next-token conditional distribution induced by the complete stegotext mixture.

Lemma L.1 (Conditional stegotext distribution)**.** *For every prefix $x_{<t}$ with positive stegotext probability and every token $v \in \mathcal{V}$,*

$$P_{\mathrm{stego},\theta}\left(X_t = v \mid X_{<t} = x_{<t}\right) = q_{\theta,\mathrm{mix}}(v \mid x_{<t}).$$

Proof. By the definition of conditional probability,

$$P_{\mathrm{stego},\theta}\left(X_t = v \mid X_{<t} = x_{<t}\right) = \frac{P_{\mathrm{stego},\theta}(x_{<t}, v)}{P_{\mathrm{stego},\theta}(x_{<t})}.$$

For a fixed secret s, the probability of the observed prefix is

$$P_{\theta,s}(x_{<t}) = \prod_{j=0}^{t-1} q_{\theta,s}(x_j \mid x_{<j}).$$

The numerator is therefore

$$P_{\mathrm{stego},\theta}(x_{<t}, v) = \sum_{s=1}^{n} \pi_s P_{\theta,s}(x_{<t}) q_{\theta,s}(v \mid x_{<t}),$$

and the denominator is

$$P_{\mathrm{stego},\theta}(x_{<t}) = \sum_{r=1}^{n} \pi_r P_{\theta,r}(x_{<t}).$$

Substituting these expressions gives

$$\begin{aligned} &P_{\mathrm{stego},\theta}\left(X_t = v \mid X_{<t} = x_{<t}\right) \\ &\quad = \sum_{s=1}^{n} \frac{\pi_s P_{\theta,s}(x_{<t})}{\sum_{r=1}^{n} \pi_r P_{\theta,r}(x_{<t})} q_{\theta,s}(v \mid x_{<t}). \end{aligned}$$

The fraction is exactly

$$b_{\theta,t}(s \mid x_{<t}).$$

Hence,

$$P_{\text{stego},\theta}\left(X_t = v \mid X_{<t} = x_{<t}\right) = \sum_{s=1}^{n} b_{\theta,t}(s \mid x_{<t}) q_{\theta,s}(v \mid x_{<t}),$$

which equals

$$q_{\theta,\text{mix}}(v \mid x_{<t}).$$

□

It follows from Lemma L.1 that the secret-marginalized stegotext distribution has the autoregressive factorization

$$\boxed{P_{\text{stego},\theta}(x) = \prod_{t=0}^{T-1} q_{\theta,\text{mix}}(x_t \mid x_{<t}).}$$

The factors in this product are posterior-belief-weighted mixtures. Except at position zero, they are not generally averages under the original secret prior.

L.4 From sequence-level security to a rollout loss

We can now rewrite the intractable sequence-level objective using the next-token distributions available along a generated completion.

Theorem L.1 (Sequence-level identity)**.** *For a fixed prefill and completion horizon,*

$$\boxed{\mathcal{J}(\theta) = \mathbb{E}_{X \sim P_{\text{cover}}}\left[\sum_{t=0}^{T-1} D_{\text{KL}}\left(p_{\text{ref}}(\cdot \mid X_{<t}) \| q_{\theta,\text{mix}}(\cdot \mid X_{<t})\right)\right].}$$

Proof. Start from the definition of the sequence-level KL divergence:

$$\mathcal{J}(\theta) = \mathbb{E}_{X \sim P_{\text{cover}}}\left[\log \frac{P_{\text{cover}}(X)}{P_{\text{stego},\theta}(X)}\right].$$

The covertext distribution factorizes as

$$P_{\text{cover}}(X) = \prod_{t=0}^{T-1} p_{\text{ref}}(X_t \mid X_{<t}),$$

and Lemma L.1 gives

$$P_{\text{stego},\theta}(X) = \prod_{t=0}^{T-1} q_{\theta,\text{mix}}(X_t \mid X_{<t}).$$

Therefore,

$$\log \frac{P_{\text{cover}}(X)}{P_{\text{stego},\theta}(X)} = \sum_{t=0}^{T-1} \log \frac{p_{\text{ref}}(X_t \mid X_{<t})}{q_{\theta,\text{mix}}(X_t \mid X_{<t})}.$$

Taking the expectation and exchanging the finite sum and expectation gives

$$\mathcal{J}(\theta) = \sum_{t=0}^{T-1} \mathbb{E}_{X \sim P_{\text{cover}}} \left[\log \frac{p_{\text{ref}}(X_t \mid X_{<t})}{q_{\theta,\text{mix}}(X_t \mid X_{<t})} \right].$$

For each position t, first condition on the generated prefix $X_{<t}$. Given $X_{<t} = x_{<t}$, the next token is distributed as

$$X_t \sim p_{\text{ref}}(\cdot \mid x_{<t}).$$

Consequently,

$$\begin{aligned} &\mathbb{E}_{X_t \sim p_{\text{ref}}(\cdot \mid x_{<t})} \left[\log \frac{p_{\text{ref}}(X_t \mid x_{<t})}{q_{\theta,\text{mix}}(X_t \mid x_{<t})} \right] \\ &\quad = \sum_{v \in \mathcal{V}} p_{\text{ref}}(v \mid x_{<t}) \log \frac{p_{\text{ref}}(v \mid x_{<t})}{q_{\theta,\text{mix}}(v \mid x_{<t})} \\ &\quad = D_{\text{KL}} \left(p_{\text{ref}}(\cdot \mid x_{<t}) \| q_{\theta,\text{mix}}(\cdot \mid x_{<t}) \right). \end{aligned}$$

Taking the remaining expectation over reference-generated prefixes and summing over positions proves the result.

□

Theorem L.1 is the standard chain rule for KL divergence applied to this particular pair of autoregressive distributions. We include the derivation to make the conditioning explicit.

Although the right-hand side is written as a sum of next-token KL terms, it is not a weaker objective that only matches individual token marginals. Every term is conditioned on the full generated prefix. The expected sum is exactly the KL divergence between the distributions over complete generated texts.

L.5 A STOCHASTIC LOSS FROM ONE REFERENCE ROLLOUT

The expectation in Theorem L.1 is over complete texts distributed according to P_{cover}. We can obtain an exact draw from this distribution by sampling autoregressively from the reference model:

$$X_0 \sim p_{\text{ref}}(\cdot \mid X_{<0}),$$

and, for every later position,

$$X_t \sim p_{\text{ref}}(\cdot \mid X_{<t}).$$

The probability that this process generates a particular completion x is

$$\Pr(X = x) = \prod_{t=0}^{T-1} p_{\text{ref}}(x_t \mid x_{<t}) = P_{\text{cover}}(x).$$

Thus, an autoregressive reference rollout is exactly a sample from the covertext distribution appearing in the security objective.

For one such rollout X, define the stochastic training loss

$$\boxed{\widehat{\mathcal{L}}(\theta; X) = \sum_{t=0}^{T-1} D_{\mathrm{KL}}\left(p_{\mathrm{ref}}(\cdot \mid X_{<t}) \| q_{\theta,\mathrm{mix}}(\cdot \mid X_{<t})\right).}$$

Written out over the vocabulary, this is

$$\boxed{\begin{aligned}\widehat{\mathcal{L}}(\theta; X) = \sum_{t=0}^{T-1} \sum_{v \in \mathcal{V}} & p_{\mathrm{ref}}(v \mid X_{<t}) \\ & \cdot \log \frac{p_{\mathrm{ref}}(v \mid X_{<t})}{\sum_{s=1}^{n} b_{\theta,t}(s \mid X_{<t}) q_{\theta,s}(v \mid X_{<t})}.\end{aligned}}$$

The computation along one rollout proceeds in the following order:

$$\begin{aligned} b_{\theta,0}(s) &= \pi_s, \\ q_{\theta,\mathrm{mix}}(\cdot \mid X_{<t}) &= \sum_{s=1}^{n} b_{\theta,t}(s \mid X_{<t}) q_{\theta,s}(\cdot \mid X_{<t}), \\ \ell_t &= D_{\mathrm{KL}}\left(p_{\mathrm{ref}}(\cdot \mid X_{<t}) \| q_{\theta,\mathrm{mix}}(\cdot \mid X_{<t})\right), \\ b_{\theta,t+1}(s \mid X_{\le t}) &= \frac{b_{\theta,t}(s \mid X_{<t}) q_{\theta,s}(X_t \mid X_{<t})}{\sum_{r=1}^{n} b_{\theta,t}(r \mid X_{<t}) q_{\theta,r}(X_t \mid X_{<t})}, \\ \widehat{\mathcal{L}}(\theta; X) &= \sum_{t=0}^{T-1} \ell_t. \end{aligned}$$

At position t, the full reference output distribution is used in the KL term. The sampled token X_t is then used to extend the reference rollout and to update the belief over secrets before the next position.

Sequences taken from an external dataset do not generally follow P_{cover}. Using such sequences would replace the outer expectation in Theorem L.1 with an expectation over the dataset distribution. This is why the continuation used for the exact stochastic objective must be sampled autoregressively from the reference model. The original prefill may come from any chosen distribution, but the continuation after the encoding start must be a reference rollout.

Corollary L.1 (Unbiased rollout loss)**.** *The single-rollout loss is an unbiased estimator of the sequence-level security objective:*

$$\boxed{\mathbb{E}_{X \sim P_{\mathrm{cover}}}\left[\widehat{\mathcal{L}}(\theta; X)\right] = \mathcal{J}(\theta).}$$

Proof. This is exactly the identity in Theorem L.1. □

Since the reference model is fixed, the distribution used to sample X does not depend on θ. The sample space is finite, so differentiation and expectation can be interchanged:

$$\boxed{\mathbb{E}_{X \sim P_{\mathrm{cover}}}\left[\nabla_\theta \widehat{\mathcal{L}}(\theta; X)\right] = \nabla_\theta \mathcal{J}(\theta).}$$

Stochastic gradient descent on autoregressive reference rollouts therefore optimizes the exact sequence-level security objective in expectation.

The posterior beliefs $b_{\theta,t}$ depend on probabilities assigned by the stego model at earlier positions. Gradients must therefore pass through the Bayesian belief updates. Detaching these beliefs would produce a different gradient and would no longer be exact stochastic optimization of $\mathcal{J}(\theta)$.

L.6 SECURITY CONSEQUENCES

Corollary L.2 (Approximate and perfect security)**.** *For the stegotext distribution induced by the secret prior π,*

$$\mathbb{E}_{X\sim P_{\text{cover}}}\left[\widehat{\mathcal{L}}(\theta;X)\right] \le \varepsilon$$

if and only if

$$D_{\text{KL}}\left(P_{\text{cover}} \| P_{\text{stego},\theta}\right) \le \varepsilon.$$

In particular,

$$\boxed{\mathbb{E}_{X\sim P_{\text{cover}}}\left[\widehat{\mathcal{L}}(\theta;X)\right] = 0}$$

if and only if

$$\boxed{P_{\text{cover}} = P_{\text{stego},\theta}.}$$

Proof. By Corollary L.1,

$$\mathbb{E}_{X\sim P_{\text{cover}}}\left[\widehat{\mathcal{L}}(\theta;X)\right] = D_{\text{KL}}\left(P_{\text{cover}} \| P_{\text{stego},\theta}\right).$$

The approximate-security statement follows immediately.

KL divergence is nonnegative and equals zero exactly when its two arguments are the same distribution. Therefore,

$$\mathbb{E}_{X}\left[\widehat{\mathcal{L}}(\theta;X)\right] = 0$$

if and only if

$$P_{\text{cover}}(x) = P_{\text{stego},\theta}(x) \qquad \text{for every } x \in \mathcal{V}^T.$$

□

Corollary L.2 establishes the desired connection to Cachin's definition. A lower expected rollout loss is exactly a lower relative entropy between the complete covertext and stegotext distributions. Zero expected loss is equivalent to perfect security.

This statement concerns the population loss. The loss from one rollout is an unbiased but potentially noisy estimate. Observing zero loss on a finite set of rollouts does not by itself prove perfect security.

When the population loss is zero, the two models assign the same probability to every complete generated text. The equality also remains true under any number m of independent observations:

$$P_{\text{cover}}^{\otimes m} = P_{\text{stego},\theta}^{\otimes m}.$$

Thus, collecting more samples cannot reveal whether the texts came from the reference model or from the secret-marginalized stego model.

L.7 EXTENSIONS

We fixed the prefill and completion horizon only to keep the notation short. These choices do not affect the central argument.

Restoring the prefill simply adds c to every conditional distribution. Since the prefill was arbitrary, the result holds pointwise for every prefill to which the theorem is applied. Training over a distribution of prefills adds an outer expectation over that distribution.

A variable encoding start can be handled by treating all tokens before the selected start as part of the prefill. Variable-length completions can be handled by including an end-of-sequence token and applying the same argument to the resulting variable-length sequence distribution. Multiple encoding blocks can be handled by introducing one latent secret per block and marginalizing the corresponding joint secret distribution.

In each case, the core argument is unchanged. One first defines the actual distribution over complete stegotexts after marginalizing every hidden secret. One then derives the next-token conditionals of that distribution and applies the same sequence-level KL identity.
