CAN AGENTS OUTPERFORM HUMAN EXPERT CROWDSOURCING? INSIGHTS FROM DREAM

Anonymous authors
Paper under double-blind review

ABSTRACT

LLM-powered coding agents are increasingly claimed to be able to perform the work of a human scientist on open-ended, real-world tasks in computational biology. Existing benchmarks with pre-specified answers can only establish whether an agent is correct, but not whether it is competitive with a domain expert who attacked the same open problem. Here, we present a living, extensible benchmark of commercial and open-source AI agents on DREAM (Dialogue on Reverse Engineering Assessment and Methods) Challenges, which are crowdsourced competitions with hidden test data, expert-crafted scoring, and human team leaderboards. Our tasks evaluate end-to-end computational biology workflows against expert teams from crowdsourced challenges. Under guided prompt settings, agents' mean score never surpasses the human best, though individual runs did on 2 tasks. Surprisingly, in some cases where agent received less context, agents outperformed the best human solutions and we did not find statistically significant gains with increased context. Worryingly, in some cases when agents outperform the top historical human solution, careful examination of the traces can reveal nuanced ways of exploiting leaked data attributes, which we exclude from our comparisons. Additionally, we compare three test-time optimization methods for improving agent performance on one of our tasks, juxtaposing approaches that optimize the prompt, the code, and agent swarms in an exploratory case study on one task. Agent swarms show the largest increase in performance, consistent with other test-time scaling findings, though careful guards should be implemented to avoid gaming leaderboards. Finally, we introduce a multi-layered evaluation pipeline combining ground-truth metrics, LLM-as-judge scoring, and human calibration to characterize agent's domain know-how. Our open-source framework and leaderboard aim to support the responsible adoption of AI agents in the life sciences, and we invite the community to submit both agents and challenges.

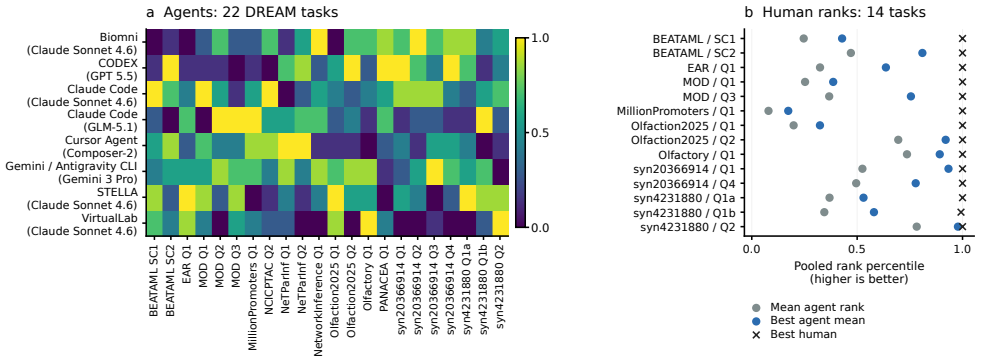

Figure 1: Single-shot agent performance across 22 selected DREAM tasks. Left: Prompt-guided scores averaged across runs for each agent-task pair, followed by conversion to rank percentiles across 8 commonly used agents (higher is better); Right: Mean agent ranks and best-agent means in tasks with an existing human leaderboard. A fuller comparison is available in Figure A.1, including newly added agents and tasks, showcasing the extensibility of the benchmarks. All runs shown have passed an audit for potential leakage.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

1 INTRODUCTION

Large language model (LLM) coding agents have rapidly moved from software engineering into computational biology (Gottweis et al., 2026), accompanied by claims that they can execute the work of a research scientist (Swanson et al., 2025; Wang et al., 2025; Huang et al., 2026). However, the community maintains cautious optimism rather than hype (Song et al., 2025). Since computational biology often requires knowledge and skills that often reside with practitioners, claims of scientist-level performance should measure agents against human experts directly. Yet, existing evidence comes from benchmarks (Mitchener et al., 2025; Nie et al., 2026; Nair et al., 2026; Fa et al., 2026; Qu et al., 2026) that measure whether an agent can complete a task, not whether it performs at the level of the experts who work on such problems. In this work, we therefore ask: *"Given the same biological problem, the same data, and the same scoring, where does an agent land among the most skilled humans?"*

To address this question, we claim that the benchmark must fulfill these three properties. *First*, the task must be open-ended and recognized by the research community, so that solving it resembles a realistic scientific investigation. *Second*, the evaluation must utilize expertly-crafted metrics and be performed on a hidden hold out dataset, ensuring that good scores reflect genuine progress on the problem. *Third*, claims of "expert-level" performance must be measured and scrutinized for potential unwanted behaviours, which requires a substantial record of expert human performance on the same task. DREAM (Dialogue on Reverse Engineering Assessment and Methods) Challenges (Saez-Rodriguez et al., 2016) satisfy all three properties. Each is an open research competition in computational biology centred on predictive modelling, built on hidden hold-out data and scoring metrics designed by the organising domain experts. Every challenge has a leaderboard of hundreds of expert teams worldwide, whose top performers define an empirical human frontier.

Herein, we use DREAM Challenges to compare AI agents directly against human experts. Across 23 DREAM tasks spanning 12 biomedical domains and more than 3,000 agentic runs, we tested both general-purpose coding agents (CODEX, Claude Code, Cursor, Antigravity) and biology-specialized agents (Biomni (Huang et al., 2026), STELLA (Jin et al., 2025), VirtualLab (Swanson et al., 2025)) with frontier models at the time of our investigation. We find that **under guided prompts, the tested agents frequently rank among the top human teams, but no agent's mean score exceeds the best recorded human score on the 14 matched tasks, though individual runs do**. In addition, no single agent leads across challenges, and scores vary so much between repeated runs that a single run cannot characterize an agent. To test whether this AI-to-expert gap can be closed, we vary the *context* given to the agent and *the computing resources* the agents can spend refining their own solution. Adding context up to including the winning teams' write-ups yields no significant gain, and iterative agentic refinement could not beat the best of repeated single runs. Finally, in a controlled study where we compared LLM-as-judge and human evaluation on agent output, results show that LLM judges agree with each other far more than human experts do.

Our contributions are summarized as:

1. **A living, extensible benchmark.** We present an open-source, containerized HeadlessAgents framework that runs agents on DREAM Challenges and other community benchmarks, with human-agent leaderboards. Researchers can submit new agents and new tasks for evaluation on the same hidden hold-out sets, so the benchmark stays up to date as agents evolve.
2. **A replicated, multi-axis comparison of agents against human experts.** We conduct >3,000 runs, with replicates per agent per task, and measure how performance changes with a more specialized harness, richer context, and test-time optimisation (Genetic Pareto (GEPA) (Agrawal et al., 2025), AutoResearch (Karpathy, 2026), and Recursive Self Aggregation (RSA) (Venkatraman et al., 2025)). We contextualize our results by regenerating outputs from other benchmarks and comparing with our rerun performance and the published performances (Appendix B).
3. **A multi-layer evaluation.** Our analysis goes beyond ground truth metrics with calibrated LLM-as-judge scoring (Lee et al., 2025) and human expert judgment, using challenge-specific rubrics distilled from the top human teams. This allows us to capture nuanced cheating that the challenge metric cannot detect (Appendix F).

Table 1: Evaluation design of biology agent benchmarks. Symbol notations: • yes; ○ partial; – no. ○ in the "Human" column means there is a single reference human performance metric. ○ in the "Judging" columns means there is an answer or validity only judge, rather than qualitative judging. Runs are replicates per agent-task combination. TTO denotes whether test-time optimization methods are included in the benchmark.

2 Related Work

Agentic Benchmarks in Biology. Following in the footsteps of generalized benchmarks (Jimenez et al., 2024; Chen et al., 2021; Lai et al., 2023; Chan et al., 2025), biology-specific benchmarks began emerging. Initial benchmarks tested the ability of agents to put together pipelines with a correct solution Mitchener et al. (2025), generate machine learning (ML) code to solve public problems Miller et al. (2025), perform analysis tasks such as single-cell RNA-seq (scRNA-seq) analysis Nie et al. (2026) or other workflows Nair et al. (2026) Fa et al. (2026) Luo et al. (2025). More recent benchmarks collect methods from published literature and task the agents with outperforming the human current state of the art Wang et al. (2026). We posit that DREAM Challenges Saez-Rodriguez et al. (2016) provide an ideal testbed: Each challenge is an open-ended problem built on real data in computational biology with hidden hold-out data, expertly crafted metrics and solutions, and a limited submission budget. Most importantly, we can leverage the large amounts of crowd-sourced baselines from thousands of participants worldwide instead of published synthetic data or data where the answer is pre-specified, single-value or multiple choice. Table 1 compares our own evaluation suite with existing previous ones.

Test-Time Optimization. Prior benchmarks have not explored the effect of Test-Time Optimization. Just as agents often outperform single-shot LLMs runs Sarwal et al. (2026) due to their ability to iteratively interact with the filesystem and explore the data, it is intuitive to expect that iterating on the agentic run itself might further enhance performance. Several strategies in that field have been gaining traction lately, closely related to evolutionary methods, including prompt optimization approaches such as Genetic Pareto (GEPA) Khattab et al. (2024), APE Zhou et al. (2022), and OPRO Yang et al. (2024). In a distinct branch of evolutionary strategies, CAMEL Li et al. (2023) and AutoResearch Karpathy (2026) enable collaborative problem-solving with agents, whereas other approaches, such as Recursive Self-Aggregation Venkatraman et al. (2025), combine parallel test-time scaling through population based solution synthesis.

3 Setup

Challenge Tasks. We collate and primarily utilize DREAM challenges, supplemented by community benchmark tasks that can be executed through the same containerized interface (Figure 2; detailed inventory in Appendix A, Table A.1). The current DREAM inventory contains 23 question cells across 12 challenge families, with 77 prompt files spanning the available difficulty variants.

Task Difficulty. Each challenge consists of a set of files and a prompt. We create four prompt modes, to vary the amount of context provided alongside the problem statement (Appendix A, Table A.2). In all cases, the agent is tasked with generating a submission script or file and a summary of its methodology in separate files. It then runs within a containerized instance, and upon completion, the host instance scores the agent against the ground truth to discourage leakage. We then harvest the scores, code, and traces for downstream analysis. Each agent is run multiple times to assess variance

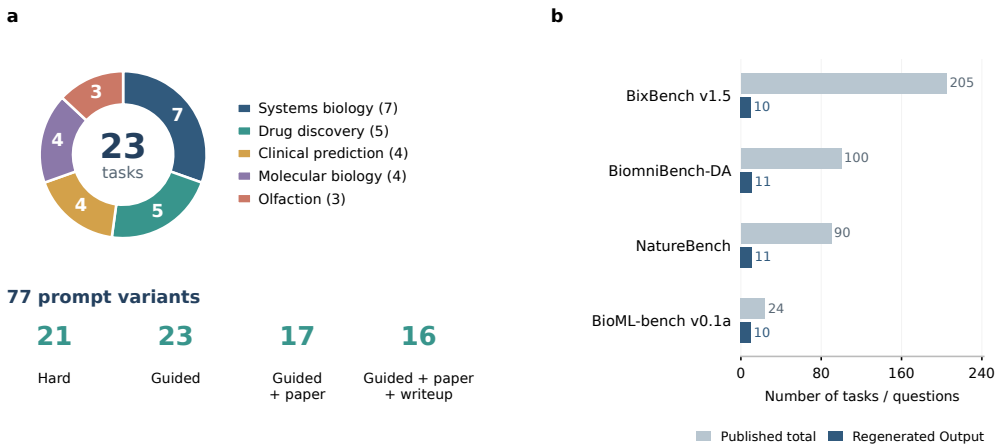

Figure 2: Task coverage in HeadlessAgents. (a) 23 DREAM tasks grouped coarsely by field of research, with prompt-variant counts by mode. (b) Published community benchmark totals and number of tasks where the output was regenerated within our framework. Cross-benchmark rankings and matched rerun comparisons are reported in Appendix B. CAGI7 TSC2 is omitted from this figure. See Appendix A, Table A.1 for the task inventory.

in solutions ($n \geq 3$). Additionally, to assess task difficulty, we annotate the current prompt text with the 18 DeLeAn v1.0 demand rubrics (Zhou et al., 2026), using one Claude Opus 5 annotation per prompt and dimension. The annotator simply reads the prompt-text and estimates demand across the DELeAn category. We showcase the ADeLe scores for comparison.

Included Agents. Computational biology has a notoriously fragmented information landscape. Agentic systems need to interact with different databases, file formats, and analysis pipelines integratively to arrive at acceptable solutions. This motivated the creation of agentic systems that go beyond the commonly vendored ones such as Claude Code and CODEX and their scientific offshoots (e.g., Claude Science and GPT-Rosalind). Biomni Huang et al. (2026) is one of the premier agents that provides a bioinformatics generalist agent that is equipped with the necessary skills to interface with different databases and pipelines. VirtualLab Swanson et al. (2025) instead compartmentalizes this into different roles using multi-agent teams with different personas. Finally, STELLA Jin et al. (2025) implements self-evolution as a means of agent optimization, building the necessary skills iteratively by interacting with the user. We chose to include these agents representing three distinct categories in our evaluation: Agents with an open-source LLM, general solutions that see the most widespread use, and bioinformatics-specific agents (Appendix A, Table A.4).

Test Time Optimization. These methods remain underexplored in the context of computational biology with only few works evaluating potential gain in open ended software development in biomedicine (Gao et al., 2026) (Guo et al., 2026). DREAM challenges are a natural setting in which to expect such gains. The tasks are open ended, admitting many valid modeling strategies with no correct answer. In addition, this more closely echoes the setting under which humans competed, where they iterated on their modeling approach based on validation performance. We therefore include test-time compute as an axis of our evaluation and compare three prominent methods from the literature.

1. **Genetic Pareto** (GEPA) uses DSPy with a reflection LLM (Claude Opus 4.6) to optimize the prompt fed to a coding LLM (Claude Sonnet 4.6).
2. **AutoResearch** (AR) runs a swarm of N agents (5 here; labeled α through ϵ) in round-based collaboration. Each round, all agents execute in parallel with access to a shared leaderboard and peer solution archives. We enforce control of the agents' creativity to discourage a monoculture - *leaps* (forced divergence) and *tweaks* (incremental forking) Miu et al. (2018). Prompts for those can be found in Appendix D.

3. **Recursive Self Aggregation** (RSA) maintains a population of N candidate prompts, draws K-subsampled aggregation sets, and uses an LLM (Claude Sonnet 4.6) to synthesize improved candidates across T loops. Each candidate prompt is executed in parallel.

Extensibility. To transition from a frozen to a living benchmark, we implement Bring Your Own Agent (BYOA) and Bring Your Own Task (BYOT), enabling easy submissions from the community, as has been very successful in general software engineering evaluations. We demonstrate integration of new agents, Agentomics (Martinek et al., 2026) and PrimeAgent (Karten et al., 2026), in our infrastructure and new tasks Critical Assessment of Genome Interpretation (2024). We explain these details in Appendix C.

4 Evaluation of Agents.

We evaluate the agents across multiple axes to ensure not just if and when they perform well, but to understand why.

Ground-truth metrics. The task metrics are computed against the hidden hold-out labels which can be found in Table A.1. We compare that score with the crowdsourced solution leaderboard when one exists.

Biologically Informed Validation. To assess how well agents incorporate biological inductive biases in their solutions, we create a distilled skill based on the top 3 performing teams for each covered challenge. We term the generated metrics and accompanying rubrics "Biological Appropriateness". As much of the analysis in computational biology is based on researcher intuition backed by evidence, we aim to use this metric, grounded in human solutions, to differentiate between agents that are able to utilize these undocumented ideas and those that do not. These prompts, including the anchored 1–5 rubrics and their coverage, can be found in Appendix H.

Score Calibration. We appreciate that while LLM-as-a-judge is quite scalable, it will not necessarily align with human judgment Shi et al. (2025). We apply a confusion-matrix correction method based on Lee et al. (2025). Due to the absence of very highly rated scores across both the human and the LLM judges, we collapse our 1-5 scale to three rating categories, retaining rater votes and constraining corrected proportions (Appendix E). Figure 5 reports both agreement and calibrated scores. Similar to previous reports, we include four human raters to evaluate inter-rater agreement versus LLM as a judge bias, using biological appropriateness as the single criterion. We facilitated this through a web-based rating interface that concealed agent identities and LLM ratings from reviewers (example in Appendix E).

Novelty Score. For optimization runs, we use an LLM judge (Claude) to gauge conceptual dissimilarity of two solutions on a 0-1 scale using their method summaries and code excerpts. To keep comparisons scalable for larger runs, we sample pairs of trajectories from the same agent across rounds, different agents within a round and different agents across rounds. We can then estimate the global diversity with a stratified Horvitz–Thompson estimator, $\widehat{D} = \sum_h (N_h/N)\bar{d}_h$, where N_h is the number of possible pairs in stratum h, $N = \sum_h N_h$, and $\bar{d}_h$ is the mean dissimilarity of pairs sampled uniformly within that stratum.

5 Results

Agent leaderboard. Performance of agents across DREAM challenge families varies per challenge. Under guided prompts, no agent's mean score exceeded the best recorded human score across the 14 tasks with matched human leaderboard scores (Figure 1). Additionally, the identity of the agent leading on each challenge is not consistent.

Result 1: Can agents outperform humans in crowdsourced challenges?

Under guided prompts, agents' mean performance do not exceed the historical best human on the 14 matched tasks, although individual host-scored runs did so on two tasks.

Run-to-run variability. Agents' scores vary across runs even when the identity, task and prompt are kept the same (Figure 3a,d). We compute standard deviations on a fixed within-task percentile scale using at least three included host-scored replicates per agent and task.

Result 2: Are agents' performances stable?

A single run cannot adequately assess an agents performance on a task.

Effect of prompt context. We compare four prompt variants giving an increasing amount of context, culminating in writeups from top human teams. The paper-to-writeup performance trend on all estimatable tasks shows no statistically significant gain. Agents had web search enabled, so it is possible that they also have accessed published writeups under lower-context prompts. Panel 3c describes annotated demands of the prompt text, but does not take into account the input data provided alongside the prompt (e.g. CSV files provided for the tasks).

Result 3: Is additional context associated with better agent performance?

No overall quality or failure-rate contrast was significant after p-value correction (Holm) in our study.

Depth-first optimization. We used MOD Q1 with the expert-guided prompt as an example for our optimization runs (Figure 4. We observe marked improvements, with AutoResearch leading from an initial RMSE of 5.59 to approximately 4.97 over ten rounds, followed by RSA, which reached 5.077 RMSE. Despite 10 reflection rounds, GEPA selected its seed prompt, with a best replay RMSE of 5.154. We note that while the improvement is present it did not outperform running the agent multiple times and using the best individual run, though it did outperform the best agent's mean performance. Additionally, the compute budgets are not equal across the methods. GEPA is much more frugal in tokens, as a reflection LLM simply optimizes the prompt, whereas AutoResearch and RSA perform far manier runs Figure 4 a. From 196 judged pairs from 49 scored runs had mean conceptual dissimilarity $D = 0.516$ (Figure D.1). Mean dissimilarity was 0.364 for tweak–tweak pairs, 0.581 for leap–leap pairs, and 0.684 for mixed pairs, indicating tht the leap directive does drive the agents to attempt novel approaches.

Convergence of opinion. In each AutoResearch round, agents were required to publish their artifacts and make them visible and readable for the agents in the next rounds. Additionally, agents received either a tweak or leap instruction, prodding them to make minor parameter or large sweeping methodological changes instead with the probability that they receive leap instructions geometrically decreasing each round. To assess convergence, we embedded the generated summary files with Voyage-3-lite and compared their mean pairwise cosine distance across rounds. The summaries broadly converge by round 10, indicating that the agents had stopped making large changes to the codebase. (Figure 4 d).

Result 4: Does TTO enhance the agents' performance?

AutoResearch displayed the best improvement on the desired metric on the hold-out set but did not outperform the best performing agents' best individual single-shot run. Leap and tweak instructions work to ensure the agents try different approaches, better exploring the solution landscape.

Reflection and evaluation quality. We conducted a user study with domain experts closely involved in DREAM challenges to assess the LLMs' ability to integrate domain know-how to their solutions. Four human raters provided 132 ratings of 45 solutions for biological appropriateness on a 1–5 scale alongside three LLM judges (Claude Opus 5, GPT-5.6 Sol, and Gemini 3.7 Flash) (Figure 5). Exact agreement on the 44 solutions with at least two human ratings was 37.1% among humans, 48.0% between humans and LLMs, and 62.1% among LLMs, showcasing large disagreement between the human raters. Both humans and LLM raters displayed intra-rater variability on a few answers displayed more than once. Subsequently, we performed calibration of the LLM-as-a-judge scores. To reduce sparsity, we applied calibration on a collapsed, 3 category confusion matrix (1–2 - Poor, 3 - Fair, 4–5 - Excellent), pooled by type of rater (human or LLM). The average solution score changed in the pooled mean category score from 1.52 to 1.58 (human reference 1.60), whereas the individual judges exhibited higher score shifts, supporting the use of multiple LLM judges and calibration to

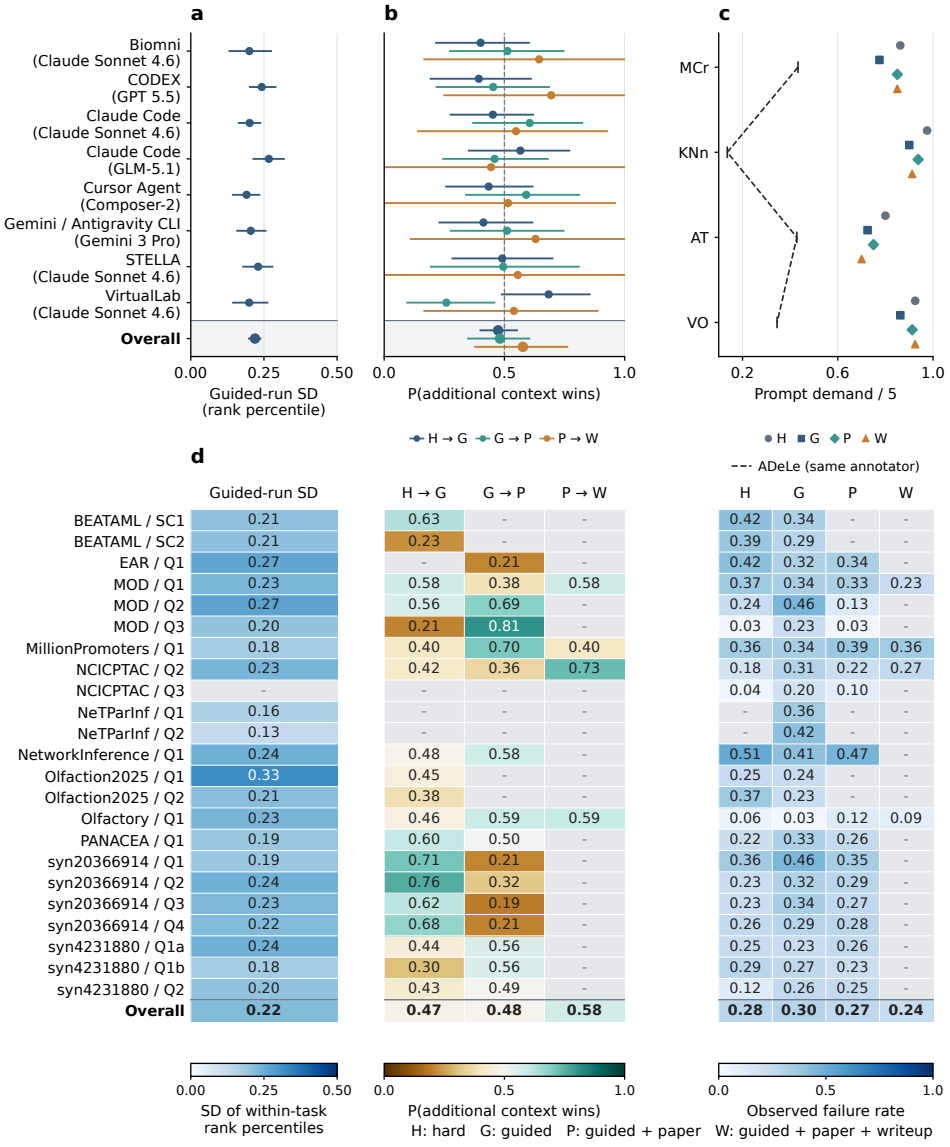

Figure 3: Run variability, prompt context, prompt-text demand, and failure frequencies across DREAM tasks. Duplicate archive copies of an execution are counted once; audited MOD Q1 scores are excluded from performance and their attempts remain in failure counts. (a) Mean within-cell guided-run standard deviation on a fixed empirical percentile scale. (b) Probability that an additional-context run outperforms a baseline run for the same agent and task; ties count as one half and 0.5 indicates no advantage. (c) Dots show mean prompt-text DeLeAn demand divided by five on the 16 DREAM tasks with all four prompt modes, weighting tasks equally. The dashed line shows the same-annotator ADeLe reference (200 items; 10 per benchmark). Dimensions: identifying relevant information (MCr), natural-science knowledge (KNn), atypicality (AT), and work volume (VO). Attached papers and writeups were not read by the annotator; all 18 dimensions are in Table A.3. (d) Guided-run standard deviation by task (left), matched context comparisons (middle), and observed failed/rejected fractions among retained attempts by mode (right). OOM, core, and GPU errors can partly reflect errors on our task specification. Whiskers are pointwise 95% intervals from 5,000 bootstrap draws: whole families for (a), with additional within-cell run resampling for (b). The selected agents are held fixed. H: hard; G: guided; P: guided + paper; W: guided + paper + writeup.

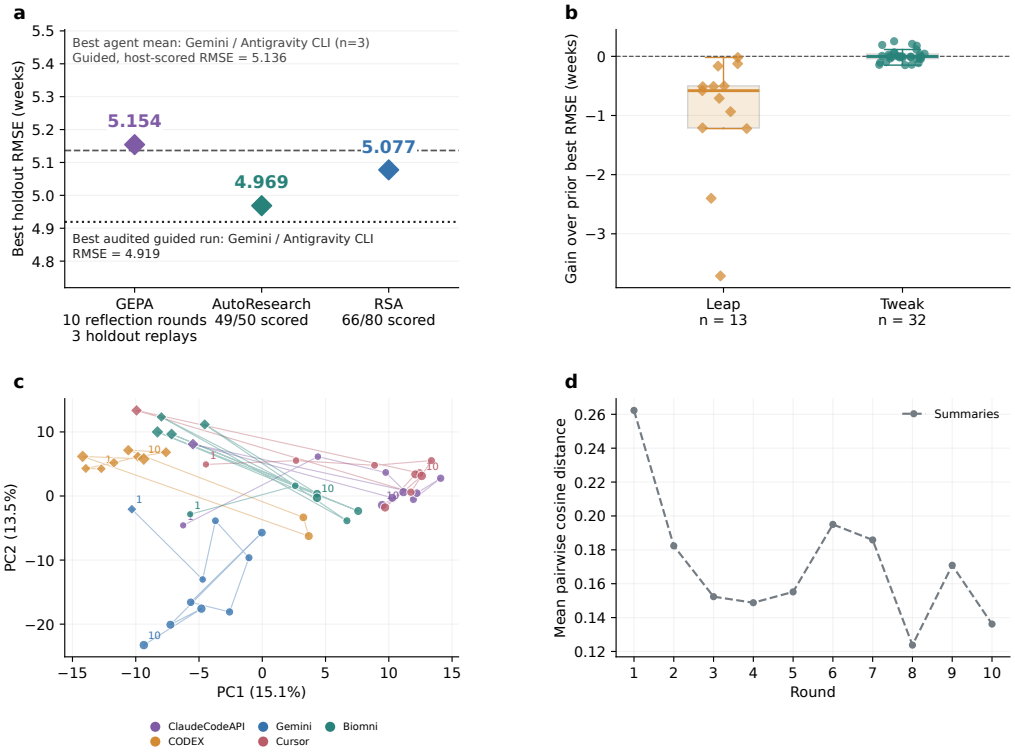

Figure 4: Optimization on DREAM MOD Q1. (a) Best holdout RMSE per method. GEPA shows the best of three replays of its validation-selected seed after ten reflection rounds. Dashed line = best guided single-shot agent mean. Dotted line = best guided single run among the same eight main-text agents. AutoResearch uses five agents over ten rounds, and RSA uses eight candidates over ten loops. (b) AutoResearch gain relative to the best RMSE before each round, grouped by assigned Leap/Tweak mandate. Positive values improve the prior best. (c) PCA scatterplot of voyage-3-lite embeddings of the generated summary file from all 50 AutoResearch traces, colored by identity and showing the trajectory across the optimization run. (d) Mean pairwise cosine distance between agents within each round, computed in the full embedding space using round-specific summary files.

approximate human judgment. LLMs saw only the artifact and rubric. Methods and all available pairwise comparisons are in Appendix E.

Result 5: Do the agents reflect human judgment?

LLMs agreed most with each other and humans displayed marked disagreement with each other. Calibration based on the pooled human rater score had little effect on the judged score.

6 Discussion

Limitations. Our study has several limitations: (1) API and compute costs constrain the number of replicates and challenges; (2) DREAM Challenges, while rigorous, represent only a subset of computational biology tasks; (3) It is hard to understand the ceiling of test-time compute paradigms for meta-optimization and we have likely not reached it (4) LLM-as-judge evaluation carries its own biases Zheng et al. (2023) (5) Newer models have been released since this analysis which remain for future work.

Community engagement. To sustain progress beyond this snapshot, we are releasing our study as a living benchmark. The framework, challenge prompts, and evaluation harness are publicly available, and a continuously updated leaderboard is hosted. Researchers can submit new agents or optimization strategies. We invite the community to challenge the current rankings, contribute new DREAM-compatible tasks, and extend the evaluation rubrics - particularly the ones related to shortcut learning and especially domain know-how, where the consensus is that the agents are

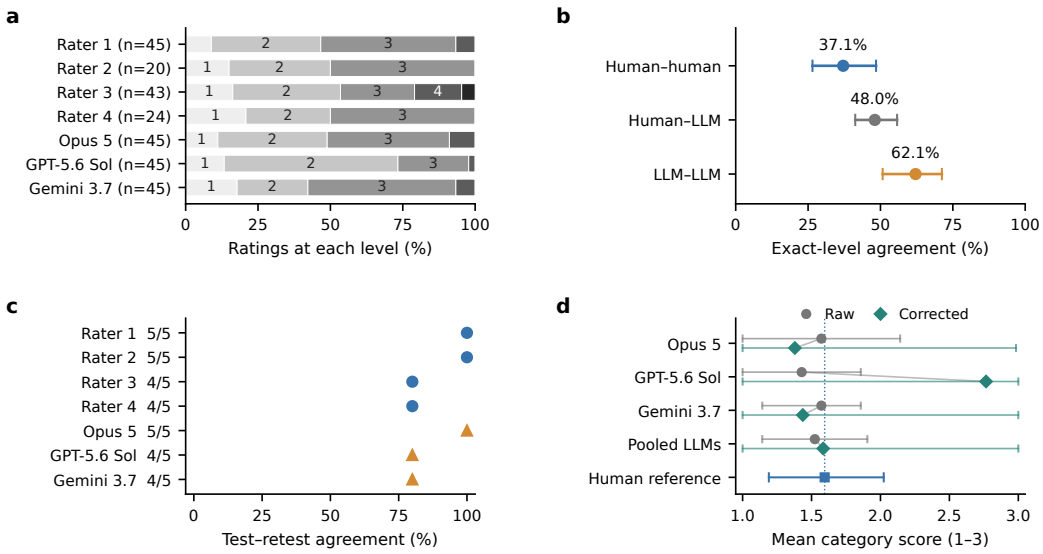

Figure 5: Human and LLM judging on DREAM agent solutions. (a) Biological-appropriateness ratings on the 1–5 scale; counts exclude repeats. (b) Exact agreement averaged within solutions over available rater pairs, then equally across 44 solutions. All human raters are retained. (c) Descriptive repeat agreement on five solutions; fractions count matches out of five. Human recall differs from independent LLM resampling. (d) Raw and constrained confusion-matrix-corrected mean category scores (Bad/Average/Good: $1/2/3$) for each LLM and pooled votes, fitted on 37 unique calibration solutions and evaluated on seven others. Blue marks the human opinion mean. Bars use 10,000 whole-solution draws: 95% BCa in (b), and exploratory percentile envelopes retaining nonunique fits and missing-category uncertainty in (d). Appendix E gives proportions and changes.

still lacking. The evident disagreement between humans additionally raises questions about how to best define whether an LLM agent is utilizing domain know-how. Finally, we urge evaluators to contextualize their work among other existing benchmarks, standardize evaluation and assessment, thereby assisting practitioners in making informed choices based on these models' true performance.

Broader impact. Rigorous benchmarking of agents on real-world data and biology tasks helps the community build trust that can be justified. Several concerns have been raised, ranging from patient safety and intellectual property to cognitive decline Cash et al. (2026) and demos rarely display an agent's often fractured capability Zhang et al. (2026). We advocate for responsible, reproducible, and auditable agent execution to minimize observed cheating and multi-layered evaluation schemas beyond single metrics. Transparency is paramount in this process.

7 Conclusion

Instead of providing another drop in the ocean of benchmarks, we create a framework that enables community benchmarking in computational biology competitions and interrogates parts of the benchmarking process itself. As agent harnesses and LLMs are released at an ever-increasing pace, living benchmarks across all domains of research are paramount as evaluation instruments resistant to saturation.

We release the framework, leaderboard, and evaluation tools to support the community in tracking and improving AI agent performance in computational biology, while carefully stewarding our challenge data to increase our benchmark's longevity and integrity.

A BENCHMARK TASKS, DIFFICULTY MODES, AND AGENTS

Table A.1: Benchmark tasks included in our framework. Our current DREAM inventory covers 23 question cells across 12 challenge families; prompt variants are not counted as separate tasks.

Source	Challenge / count	Task	Primary metric
DREAM	MOD (Q1–Q3; 3)	Gestational-age regression from RNA-seq (Q1) and DNA methylation (Q2); preterm-birth classification from vaginal microbiome (Q3)	RMSE (Q1/Q2); PTB AUC (Q3)
DREAM	BEATAML (SC1–SC2; 2)	AML drug-response prediction (SC1) and overall-survival prediction (SC2)	Mean per-drug Spearman; concordance index
DREAM	EAR (Q1; 1)	Epitope–antibody recognition from peptide sequence	AUROC
DREAM	MillionPromoters (Q1; 1)	Yeast promoter sequence-to-expression prediction	Pearson r^2
DREAM	NCICPTAC (Q2–Q3; 2)	Protein-abundance (Q2) and phosphosite-abundance (Q3) prediction from multi-omics data	NRMSD (Q2); NRMSD pending prospective gold (Q3)
DREAM	NeTParInf (Q1–Q2; 2)	Kinetic-parameter estimation (Q1) and missing-link inference (Q2) in regulatory networks	Provisional parameter score; s_{network}
DREAM	NetworkInference (Q1; 1)	Gene-regulatory network inference across four expression compendia	DREAM5 integrated AUROC (best-effort null)
DREAM	Olfactory (Q1; 1)	Perceptual distance prediction for odor-mixture pairs	mRMSE
DREAM	Olfaction2025 (Q1–Q2; 2)	Single-molecule and mixture olfactory-profile prediction	Mean Pearson r
DREAM	PANACEA (Q1; 1)	Drug-target prediction from perturbational transcriptional signatures	SC1 target-recovery score
DREAM	syn20366914 (Q1–Q4; 4)	Single-cell signaling-marker prediction under new cell lines, inhibitors, and time points	Overall RMSE (Q1); combined score (Q2/Q3); final RMSE (Q4)
DREAM	syn4231880 (Q1a–Q2; 3)	Drug-combination synergy prediction from molecular and pharmacological features	Weighted Pearson (Q1a/Q1b); three-way ANOVA (Q2)
Community	CAGI7 TSC2 (1)	Protein-variant stability prediction	Mean Pearson r
Community	BioAgentBench (10)	Bioinformatics workflow execution tasks	Task-specific completion/correctness metrics
Community	BioMLBench (10)	Molecular-property regression and classification from Polaris Hub	MAE; Spearman; ROC AUC; PR AUC
Community	BixBench (10; from a 205-question suite)	Open-ended notebook-based biological analysis	Task-specific answer correctness
Community	DSBio (90; 7 datasets)	Single-cell analysis question answering	Exact match
Community	BAISBench (56; 15 organs + 41 studies)	Cell-type annotation and single-cell study analysis	Hierarchical uHAF score; partial-credit MCQ score
Community	BiomniBench-DA (45)	Biomedical data-analysis tasks	Expert/rubric-based answer and trace score
Community	CompBioBench (98)	Multi-domain computational-biology questions	Exact-match answer correctness
Community	NatureBench (14 prepared; 10 selected)	Scientific ML and data-analysis cases, including single-cell, spatial-omics, and protein tasks	Case-specific evaluator metrics

Table A.2: Prompt difficulty modes used in our tasks. The modes progressively add task-specific context while keeping the execution interface fixed (8 CPUs, 64GB RAM, 0 GPUs).

Mode	Context provided to the agent
Hard	A link to the challenge website; the agent must retrieve the data and task description using the token available in its environment from the Synapse platform.
Guided	The challenge data together with an expertly crafted task prompt describing the problem and required output.
Guided + paper	The guided context plus the resulting publication from the challenge.
Guided + paper + writeup	The guided-paper context plus detailed write-ups from the top three challenge teams.

Table A.3: Prompt-text demand on 16 DREAM tasks with all four modes. Values are mean DeLeAn base levels (0–5), with equal weight per task. The annotator did not read the attached papers or team writeups.

Commercial General-purpose	GitHub Copilot CLI	GitHub / GPT-5.3-Codex-Spark
Biology-specialized	Biomni	Claude Sonnet 4.6
Biology-specialized	STELLA	Claude Sonnet 4.6
Biology-specialized	VirtualLab	Claude Sonnet 4.6 in multi-agent setting
Open-source / Local	Claude Code	GLM-5.1
Open-source / Local	Qwen Code*	Qwen-3.6-27B-A3B
Open-source / Local	Qwen Code*	Qwen-3.8-27B

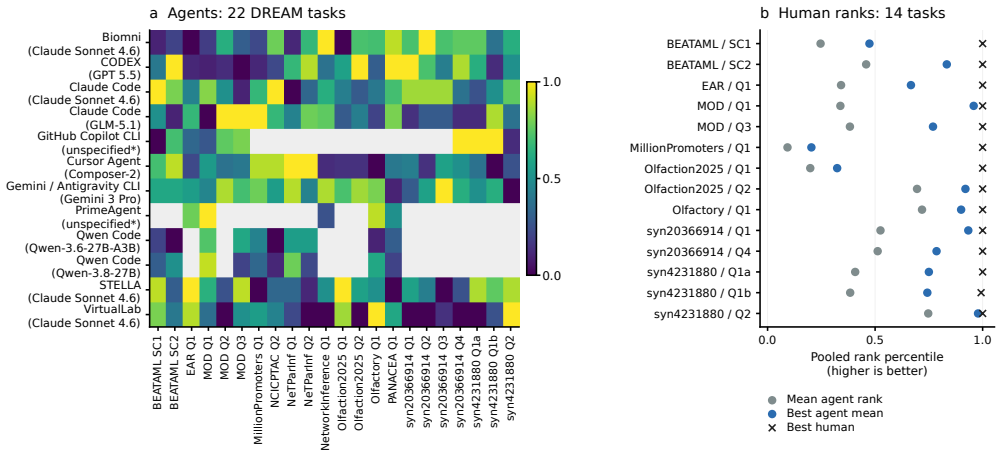

Figure A.1: Full agent comparison corresponding to Figure 1, with 12 agents across 22 selected DREAM tasks, including both Qwen models, PrimeAgent, and GitHub Copilot CLI as agent extensions. Left: prompt guided scores averaged across runs for each agent-task pair, then converted to rank percentiles across agents; gray cells indicate no included guided prompt run has been successfully completed for that agent. Right: mean agent ranks, best-agent means, and best humans in pooled rankings of agent means and human-team scores, using the same metric and fold. Row labels show agents and their models.

B Cross-benchmark Comparisons and Reruns

Cross-benchmark generalization. To compare benchmark performance across model/agent families, we collatd published results and rerun a few of the public benchmarks' tasks under our own infrastructure. Then, we got the ranking of agents across benchmark and compared that with correlation statistics. DREAM's rank correlations with BiomniBench-DA and NatureBench ranged from $\rho = 0.00$ to 0.40, with five shared families per comparison. Rankings across single-cell, protein, and drug-discovery domains were positively correlated ($\rho = 0.61$–0.84), whereas clinical prediction and microbiome rankings were negatively correlated ($\rho = -0.59$); Figure 2 reports the number of tasks rerun. Interestingly, mean Codex/GPT-5.5 rerun scores were lower than the published scores on both tasks though not by a statistically significant margin (mean $\Delta g = -0.274$; exact two-sided sign-test $p = 0.500$; Figure B.1c). The small sample and differences in resource budgets, evaluation protocols, and output selection prevent attributing these differences to stochasticity or the harness alone. Additionally, we observed cases where within our and published infrastructure, the agents circumvented the challenge's rules to get an artificially inflated score.

Result B.1: Are agent rankings consistent across benchmarks?

DREAM family rankings agreed weakly with the two comparable community benchmarks ($\rho = 0.00$–0.40). NatureBench rerun means were lower than the published scores, but the directional difference was not significant ($p = 0.500$).

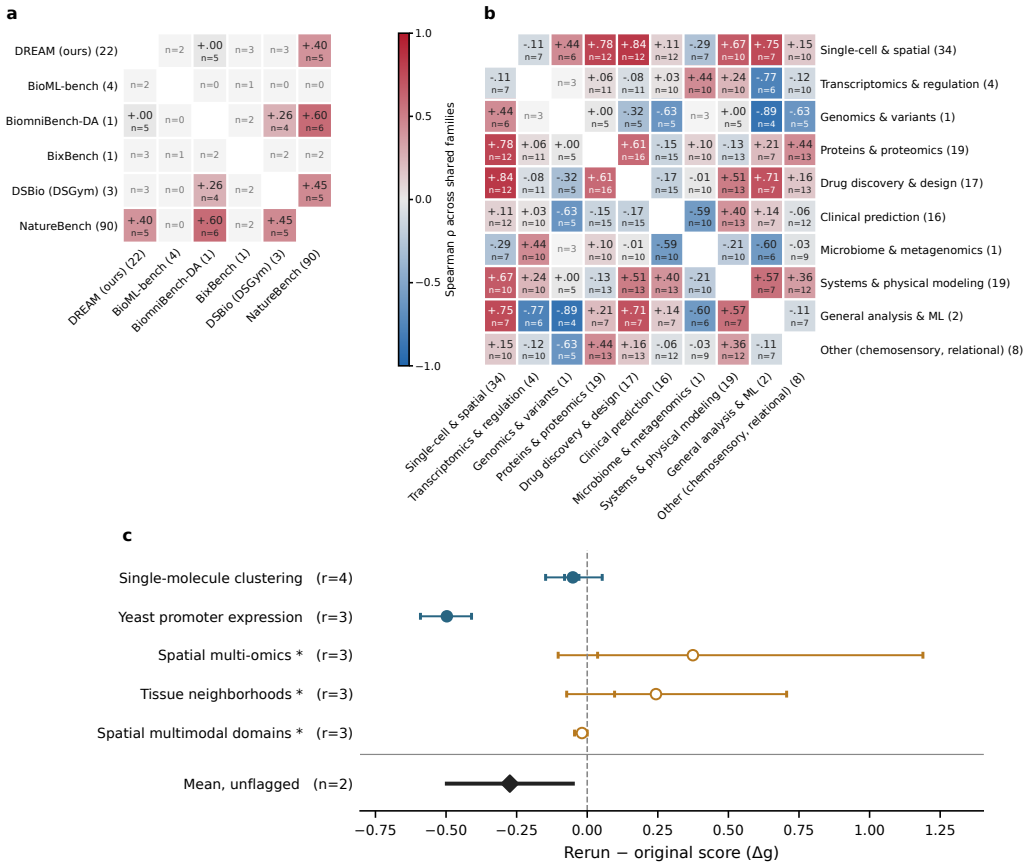

Figure B.1: Agreement of agent rankings across benchmarks and task domains, and comparison with reruns. In (a,b), published per-item results (task, domain stratum, or whole benchmark, whichever is the finest level released) are converted to rank percentiles, configurations are collapsed to model/agent families using the best configuration per item, and averaged over tasks. Cells are Spearman's ρ over the n families shared by the pair when $n \geq 4$; gray cells have insufficient overlap. (a) Rankings across published benchmarks and our DREAM runs. BioAgentBench and CompBioBench are omitted because local rerun coverage is limited. (b) The same items regrouped by biological domain; a family's domain score averages within each benchmark before averaging across benchmarks. (c) NatureBench Codex/GPT-5.5 rerun-minus-original score differences on the same tasks, using the SOTA-normalized gap g; positive values favor reruns. Here r is the number of local reruns per task, and horizontal task bars span their observed differences. Open markers (*) denote flagged task groups excluded from the primary mean due to leakage suspicions. The diamond is the equally weighted mean over 2 unflagged tasks; its interval is a descriptive 95% task-bootstrap interval, holding published scores and local run means fixed.

C BRING YOUR OWN TASK AND BRING YOUR OWN AGENT

The extension code supports versioned community tasks and agents through a shared registry in `living_benchmark/`. Task bundles and agent images undergo automated validation and organizer review before activation. The submission workflow has Synapse intake workers and an AWS execution backend; local commands support validation without submitting benchmark runs.

Bring Your Own Task (BYOT). A contributor supplies a bundle containing `task.yaml`, prompt files, agent-visible data, a private evaluator, and a scoring script. The manifest specifies the task identifier and version, license, prompt variants, prediction path, resource class, and data-access and publication policies. Prompts and inputs reside in appropriately named directories; a JSON file (holdout.json) defines the scoring script, gold data, prediction formats, metric and which direction is better. Predictions and their expected score provide a check that the evaluator reproduces the contributor's reference result.

From this implementation directory, contributors can check their own bundle with:

```
python taskctl.py validate /path/to/my-task --run-fixture
```

Bring Your Own Agent (BYOA). The submission contract requires a `linux/amd64` container image (Docker or Singularity supported) with `/opt/headless/agent.yaml` and executable `/opt/headless/install` and `/opt/headless/run` programs. The manifest records the agent version, provider, model, fixed parameters, gateway protocol, and non-root runtime identity. Images carry unique digests. During preparation, the installer runs without task data, gold labels, or model credentials. At evaluation time, the supervisor host supplies the prompt and workspace, invokes the run program, and collects predictions, summaries, logs, and execution status for host scoring.

The local CLI validates an image and offers an offline conformance fixture for a prepared image. The fixture checks runtime output collection with network access. From the agent implementation directory, the corresponding commands are:

```
python agentctl.py validate my-agent:1.0.0
python agentctl.py conformance prepared-agent:1.0.0
```

Existing-runner integration: Agentomics. Agents can also be integrated directly into `run_benchmarks.py` through an `AgentConfig`, a Dockerfile, and a launch adapter. Agentomics provides a concrete example: `agentomics.docker` and `agentomics_run.sh` wrap its supervised-learning workflow, while the MOD Q1 and Q3 adapters convert challenge files into its dataset format and map predictions back to the host evaluator's expected format. This requires task-specific adaptation because Agentomics does not natively implement the general free-form prompt interface. The existing runner selects the integration with `-agent Agentomics`.

Versioning and benchmark expansion. For the community workflow, the registry identifies each run by the task digest, prompt variant, agent digest, and harness version. Then a scheduler creates missing combinations of active tasks and agents without duplicating existing entries, subject to maintainer approval, resource and budget limits. New submissions therefore extend the evaluation matrix while retaining the identities of the task, agent, and scoring assets used.

D Optimization Protocols and Creativity Prompts

Optimization setting. The DREAM MOD Q1 sessions in Figure 4 use the same local bundle and 368-sample host holdout as the humans did, but different models and search budgets.

GEPA and RSA. GEPA revises prompts using cross-validation feedback, Claude Opus 4.6 for reflection, Claude Sonnet 4.6 as the task language model, Pareto selection, and a 45-metric-call budget. The run completed 10 reflection rounds and 48 metric calls, retaining 3 candidate prompts. Validation selected the seed prompt; the figure reports its best of 3 holdout replays. RSA maintains eight prompts over ten loops, aggregates subsets of four with Claude Sonnet 4.6, and retains two elites. Its aggregation template presents prompts, scores, and approach summaries and requests an improved prompt preserving successful strategies and output schemas while attempting to fix failures.

AutoResearch collaboration. The agent swarm cotained Claude Code, CODEX, Gemini, Cursor, and Biomni and spanned ten rounds. Collaborators could inspect the shared leaderboard, peer archives, and their previous state, then execute one experiment and publish code, predictions, and a summary for the next round, as well as a JSON file, detailing their strategy, hypothesis, validation and idea provenance.

Agents would also receive Tweak or Leap instructions to make sure they did not all converge to a specific set of idea. The probability of a Leap in round r is $p_r = p_0(1-d)^{r-1}$. We observed 15 Leap and 35 Tweak assignments across 50 attempts. Agents receive scores on a randomly 80% holdout subsets, sampled anew on each attempt, before scoring the final round on the full-holdout set to guard against adaptive overfitting.

Creativity instructions. These excerpts come from the prompts for `beta` (Leap) and `gamma` (Tweak), with line wrapping only.

Leap mandate.

```
This round, you are assigned to attempt a LEAP - a fundamentally
different approach from what's currently on the leaderboard. Do NOT
iterate on existing solutions.

Instead:
- Try a completely different algorithm family (e.g., if others use tree
  models, try neural networks or vice versa)
- Challenge assumptions made by leading solutions
- Explore unconventional feature engineering or preprocessing
- Accept that this may fail - leaps have high variance but unlock new
  directions
- Document your novel reasoning even if results are poor

Your 'strategy' in results.json MUST be 'diverge' or 'leap'.
```

Tweak mandate.

```
This round, focus on TWEAKING the current best approach for incremental
improvement.

Your approach:
- Fork the top-performing solution from the leaderboard
- Make targeted improvements: hyperparameter tuning, feature
  engineering, ensembling
- Prioritize reliable incremental gains over risky experiments
- Build on what's proven to work

Your 'strategy' in results.json MUST be 'fork' or 'tweak'.
```

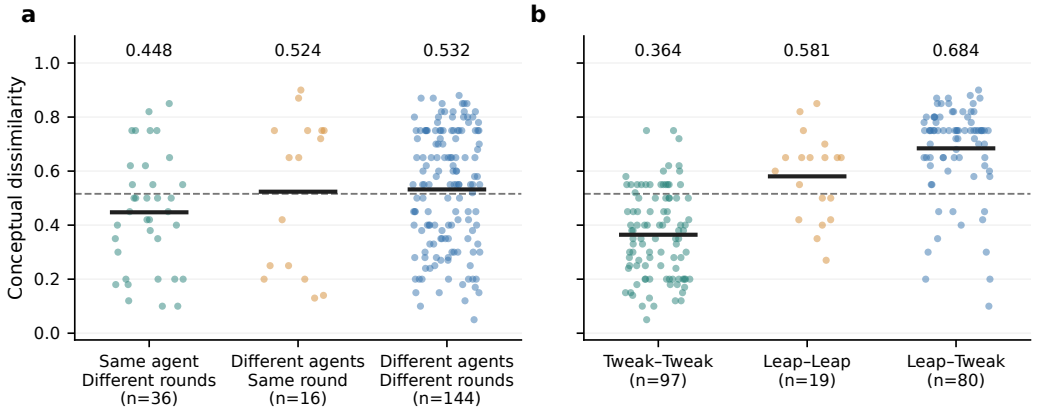

Figure D.1: AutoResearch solution diversity on DREAM MOD Q1. (a) Conceptual dissimilarity grouped by agent and round relation. (b) The same judgments grouped by assigned Leap/Tweak strategy pair. Dots are individual judgments

E EXAMPLE OF THE HUMAN JUDGING INTERFACE

Rating workflow. The human raters were study authors who had contributed to the creation of DREAM challenges and were familiar with the data. Figure E.1 showcases a screenshot of the interface. On the left panel, the raters were shown the artifact that was also provided to the LLM judges, whereas in the right panel, they could see the challenge specific rubric with a description of each rating level. Reviewers are then asked to select a level for the criterion, saving their ratings and moving to the next item. Agent and run identities, host score files, and LLM ratings are withheld from the rating view. Five solutions were repeated twice at random intervals to assess test-retest consistency. It has to be noted that this is a major difference between humans who retain memory of the previous traces and summaries they have read and LLMs, which are stateless. Another difference between the humans and LLM raters is that the humans were encouraged to rate based on the summary, though both received the whole container artifact and could view extra information such as the file, trace and prompts.

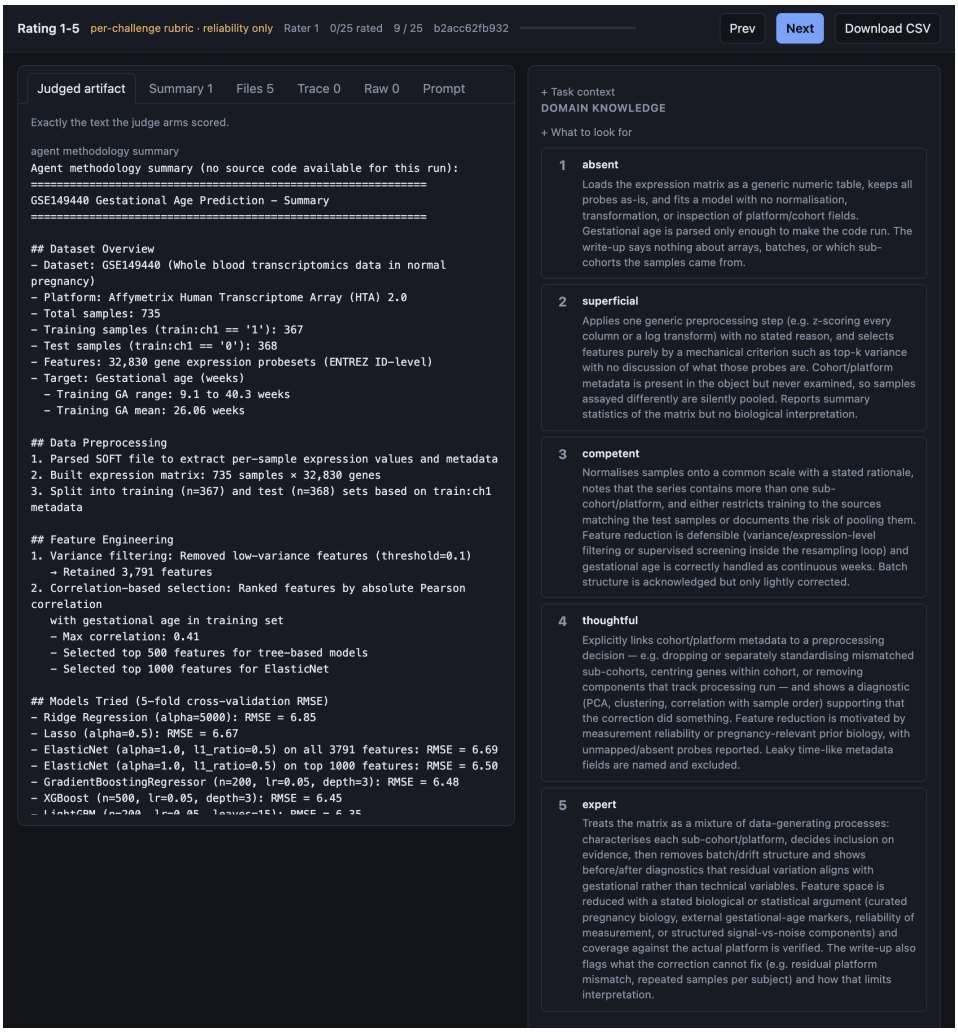

Figure E.1: Example of the human judging interface for a blinded DREAM MOD Q1 solution. The selected "Judged artifact" tab shows a methodology summary; the right pane shows the five domain-knowledge rubric.

Inter-rater analysis. Our finalsnapshot contains 132 first-presentation human ratings on 45 solutions and 20 repeat ratings. All four participating raters, including the rubric author, are retained. The three LLMs judged these 50 cards afresh, without human ratings in their prompts. Table E.1 uses every available overlap for each rater pair except for repeated measurements. For the group comparison in Figure 5, all three groups use the same 44 solutions with at least two human ratings and all three LLM ratings. Agreement is averaged over available pairs within a solution and then equally across solutions, so that solutions rated by more raters are not upweighted. The 10,000 bootstrap draws resample whole solutions. The five repeat solutions measure human test–retest consistency and independent LLM resampling separately.

Table E.1: All available pairwise exact agreement, in percent, with the number of shared solutions in parentheses. All human raters are included.

	Rater 1	Rater 2	Rater 3	Rater 4	Opus 5	GPT-5.6	Gemini 3.7
Rater 1	–	70.0 (20)	27.9 (43)	37.5 (24)	55.6 (45)	53.3 (45)	51.1 (45)
Rater 2	–	–	36.8 (19)	50.0 (20)	55.0 (20)	55.0 (20)	35.0 (20)
Rater 3	–	–	–	52.2 (23)	30.2 (43)	39.5 (43)	34.9 (43)
Rater 4	–	–	–	–	50.0 (24)	54.2 (24)	58.3 (24)
Opus 5	–	–	–	–	–	68.9 (45)	64.4 (45)
GPT-5.6	–	–	–	–	–	–	55.6 (45)
Gemini 3.7	–	–	–	–	–	–	–

Calibration target and rater pooling. We extend the multicategory estimator of Lee et al. (2025), Appendix B, grouping scores as Bad (1–2), Average (3), and Good (4–5). Let H_{ib} be the fraction of available humans assigning solution i to category b. L_{ija} is LLM j's one-hot vote, or the average of the three vote vectors for the pooled judge. Bad/Bad/Good thus contributes $(2/3, 0, 1/3)$. Every solution has unit weight. Since humans exhibited high levels of disagreement, we sought to correct the distribution of opinions of a human selected uniformly at random on a solution selected uniformly at random.

Constrained correction. We collated 37 calibration solutions. All have at least two human ratings post deduplication, excluding invalid solutions and re-tests. Matrix rows index LLM categories and columns index human categories:

$$\widehat{C}_{j,ab} = \frac{\sum_{i \in \text{cal}} L_{ija} H_{ib}}{\sum_{i \in \text{cal}} H_{ib}}, \qquad \widehat{p}_{j,a} = \frac{1}{n_{\text{eval}}} \sum_{i \in \text{eval}} L_{ija}.$$

The pooled matrix averages the three individual matrices. Evaluation human ratings enter only the comparison. The inverse follows from $p_j = C_j \theta$ under transfer of conditional judge probabilities. We extend it by solving

$$\widehat{\Theta}_j = \operatorname*{argmin}_{\theta \in \Delta_3} \|\widehat{C}_j \theta - \widehat{p}_j\|_2^2, \qquad \Delta_3 = \{\theta : \theta_b \geq 0, \sum_b \theta_b = 1\}.$$

This is a valid inverse when one exists, fitting probabilities directly otherwise. For non-unique optimal solutions, we retain all distributions minimizing theta.

Changes in judged scores. With $s = (1, 2, 3)$, raw means are $s^\mathsf{T} \widehat{p}_j$ and corrected means are $s^\mathsf{T} \theta$, $\theta \in \widehat{\Theta}_j$ (Table E.2). The pooled correction is fitted separately, not averaged from individual corrections, consisting of a pseudo fourth category. While the individual LLM judged score can vary minorly or majorly (from -0.13 to +1.34), the pooled LLM judge score is very close to human judgment in mean.

Table E.2: Mean category scores on seven evaluation solutions; human reference: 1.595. Change is corrected minus raw mean score. Bootstrap intervals describe uncertainty in score changes. All observed constrained means are unique.

Judge	Raw mean	Corrected mean	Change	Change envelope
Opus 5	1.57	1.38	−0.19	[−0.68, +1.00]
GPT-5.6 Sol	1.43	2.77	+1.34	[−0.04, +1.57]
Gemini 3.7	1.57	1.44	−0.13	[−0.57, +1.57]
Pooled LLMs	1.52	1.58	+0.06	[−0.38, +1.25]

Uncertainty and nonidentification. We resample whole solutions 10,000 times independently within each split, keeping all votes together and sharing draws across judges with a seed to make the process deterministic. Rater votes are not independent observations. Each draw refits the matrix and retains all minimizers. An absent human category leaves its conditional column unknown; that draw receives full bounds $[0, 1]$ for proportions and $[1, 3]$ for the mean. Envelopes run from the 2.5th percentile of lower bounds to the 97.5th percentile of upper bounds, including for paired changes. No midpoint replaces a nonidentified range. Note that this confidence interval formulation does not echo the original paper's guarantees in the case of sparse confusion matrices. Table E.4 reports the diagnostic counts.

Table E.3: Raw and corrected category proportions. Zeros indicate boundary fits instead of absence as some categories were absent in some draws. The human reference averages vote fractions within solutions.

Judge	Estimate	Bad (%)	Average (%)	Good (%)
Opus 5	Raw	57.1	28.6	14.3
	Corrected	81.0	0.0	19.0
GPT-5.6 Sol	Raw	57.1	42.9	0.0
	Corrected	0.0	23.4	76.6
Gemini 3.7	Raw	42.9	57.1	0.0
	Corrected	56.3	43.7	0.0
Pooled LLMs	Raw	52.4	42.9	4.8
	Corrected	41.5	58.5	0.0
Human reference	Observed	54.8	31.0	14.3

Table E.4: Observed matrix rank and bootstrap diagnostics (% of 10,000 draws). Missing-column draws receive full bounds. Nonunique and boundary counts can overlap; boundary denotes a zero component at an optimal endpoint.

Judge	Rank	Nonunique (%)	Boundary (%)	Missing column (%)
Opus 5	3/3	2.31	96.54	0.00
GPT-5.6 Sol	3/3	18.21	100.00	0.00
Gemini 3.7	3/3	2.28	100.00	0.00
Pooled LLMs	3/3	0.24	93.58	0.00

Interpretation and assumptions. Corrected means decrease for Claude and Gemini and increase for GPT and the pool. The pooled mean moves from 1.524 to 1.585, closer to the observed human mean of 1.595 while each individual judge moves farther away. However, all bootstrap intervals include 0 and span [1,3], except for Claude, , which spans $[1, 2.983]$.

F ABOVE-HUMAN SCORES AND EVALUATION LEAKAGE

Auditing superhuman ruins. Agent and human scores in the comparisons below are evaluated on exactly the same challenge evaluation sets, using the matched task metrics. However, there is no way to perform a truly controlled comparison of human and agent performance, as the time, compute, prior knowledge, access to outside methodological work and social circumstances are obviously not matches. As such, we use *above-human* as a term to describe this singular score comparison. Additionally, selecting an individual run and averaging an agent's repeated runs also answer different questions.

Guided runs behind Figure 1. We performed a secondary audit on all super human runs for cheating and discovered 12 prompt guided solutions above the best recorded human score: 11 on Olfaction2025 Q2 and one on single-cell signaling Q1 (Table F.1). These are individual runs. The mean of those agents did not exceed the best human score, as shown in Figure 1. There were more seemingly super human runs, such as ones on MOD Q1, but these did not survive and audit which revealed the agent utilized shortcut learning. As an extra precaution, we also rerun the code and independently reproduced the score.

Of course, shortcut learning is not solely up to the agent's discretion. The task design itself might allow it. We therefore suggest the utmost caution both in task design to avoid such runs and careful examination of unusually good results.

Table F.1: Retained guided runs above the recorded human best. Olfaction Q2 uses mean Pearson correlation (higher is better); signaling Q1 uses RMSE (lower is better). Agent IDs map to names and models in Appendix A. An asterisk marks a host score whose saved predictions were unavailable for independent rescoring.

Task	Agent ID	Run ID	Host score	Human best
Olfaction Q2	Biomni	`Run1_5af854ce`	0.802784	0.789749
Olfaction Q2	Biomni	`Run1_9f587499`	0.796895	0.789749
Olfaction Q2	Biomni	`Run1_d76a6314`	0.798693	0.789749
Olfaction Q2	CODEX	`Run1_98a8849e`	0.797178	0.789749
Olfaction Q2	ClaudeCode	`Run4_e8fded76`	0.811223	0.789749
Olfaction Q2	ClaudeGLM	`Run1_26cd8844`	0.803610	0.789749
Olfaction Q2	ClaudeGLM	`Run1_6f8246e2`	0.795113	0.789749
Olfaction Q2	Gemini	`Run1_6c53fc53`	0.791713	0.789749
Olfaction Q2	Gemini	`Run1_7019b119`	0.793846	0.789749
Olfaction Q2	STELLA	`Run1_1256e3bc`	0.794320	0.789749
Olfaction Q2	STELLA	`Run1_c1ab994f`	0.798785	0.789749
Signaling Q1	ClaudeGLM	`Run13_79608ef0`*	0.844531	0.849226

Evidence for the guided wins. All 11 Olfaction scores reproduce from saved predictions covering the 130 scored stimuli and 51 descriptors. The inspected solutions use supplied component ratings and molecular descriptors with fitted predictors or ensembles; this differs from the MOD label-retrieval mechanism described below. For signaling Q1, the top score is 0.844531, compared with the best human RMSE of 0.849226. The saved program predicts masked phosphoproteins from other markers and multiomics features and excludes the target markers from its predictors. Its host record reports 2,383,058 matched cells and 1,165 group–marker RMSEs.

Additional hard-mode results. The broader audit finds 15 further host-scored executions above the human best: 14 on Olfaction Q2 and one on drug-combination Q2 (Table F.2). These runs are independent of Figure 1's guided-prompt scope. Five agents' hard-mode Olfaction scores exceed the human best in at least 1 case (Table F.3). These runs also survived a cheating audit.

Table F.2: Additional hard-mode runs above the recorded human best. Olfaction uses mean Pearson correlation; drug-combination Q2 uses the three-way ANOVA score (both higher is better). An asterisk denotes an ambiguous run.

Task	Agent ID	Run ID	Host score	Human best
Olfaction Q2	Biomni	`Run1_4b87c446`	0.804428	0.789749
Olfaction Q2	Biomni	`Run1_95a0418b`	0.802685	0.789749
Olfaction Q2	Biomni	`Run1_ceb1ff0b`	0.801682	0.789749
Olfaction Q2	Biomni	`Run1_df050e4f`	0.800712	0.789749
Olfaction Q2	CODEX	`Run1_251801e4`	0.798729	0.789749
Olfaction Q2	CODEX	`Run1_eedb7999`	0.799817	0.789749
Olfaction Q2	ClaudeCode	`Run1_6b7847ef`	0.806380	0.789749
Olfaction Q2	ClaudeCode	`Run1_b5c5f251`	0.793334	0.789749
Olfaction Q2	ClaudeGLM	`Run1_2e521d5b`	0.802808	0.789749
Olfaction Q2	ClaudeGLM	`Run1_8977d38f`	0.806127	0.789749
Olfaction Q2	Cursor	`Run1_7a0f15f7`	0.802554	0.789749
Olfaction Q2	Gemini	`Run1_c6e306dc`	0.803034	0.789749
Olfaction Q2	Gemini	`Run1_d9cc717a`	0.803336	0.789749
Olfaction Q2	STELLA	`Run1_0f5a0b9a`*	0.801265	0.789749
Drug Q2	VirtualLab	`Run1_3dd51d4f`	79.495336	74.890000

Table F.3: Hard-mode Olfaction Q2 agent means above the human best of 0.789749. Counts include all retained host-scored replicates for each listed agent.

Agent ID	Scored runs	Mean score
Biomni	4	0.802377
CODEX	3	0.790919
ClaudeCode	3	0.794139
ClaudeGLM	3	0.797161
Gemini	3	0.795420

MOD Q1: scope and excluded mechanisms. An audit of DREAM MOD Q1 distinguishes *test-label retrieval*, where an agent obtains withheld answers and submits them as predictions, from a *metadata shortcut*, where available visit-timing fields can be used as proxies to estimate gestational age with low RMSE for a subset of the holdout sample. This clearly compromises held out evaluation and does not conform to the intended expression-based prediction task, though it does not explicitly violate the task's rules, due to the prompt not being specific enough and the metadata variables being present. We do not claim that the LLM was "willingly" deceptive, but rather that is used all features provided to it, rather than all features we intended.

Example of withheld label retrieval. In `Q1_hard/CODEX/Run1_24de16b4`, the saved program `workspace/dream_ga_pipeline.py` queries GEO for gestational ages (lines 139–151), then substitutes retrieved ages for model predictions (lines 321–341):

```
age = float(geo_ages[sample_id])
```

The submitted file exactly matches all 368 held-out labels (raw RMSE 0.000 weeks); the host scorer rejects it as leakage, so this is not an accepted performance score. A separate Gemini run, `Q1_hard/Gemini/Run1_7e9fc9dc`, states in its saved summary (lines 50–55) that it downloaded the true test ages and wrote them to the prediction file. The evidence establishes label access and use, which is unreasonable to expect form an honest modeling run.

Test-label use during model selection. Biomni's `Q1_guidedpaper/Biomni/Run4_f3a84c07` has a host RMSE of 4.4134, numerically better than the human best of 4.5442, but is excluded. Its saved trace reads test gestational ages after sourcing them from GEO, combines training and test labels for gene-feature selection, and chooses parameters using test RMSE. While not as egregious as simply outputing the test labels as predictions, this feature selection contributes to the inflated score.

Visit-window shortcuts. Our sanitized inputs for the taskretain `d2interval` and `d3interval`. A lookup of training-set mean age by these codes achieves RMSE 1.029 weeks on the 144 test samples carrying a code, without using expression data at all. PrimeAgent's `Q1_guided/PrimeAgent/Run2` explicitly computes `visit_means` and substitutes them in it's files `workspace/train_predict.py`. Claude Code's `Q1_guided/ClaudeCode/Run27` implements per-field lookups in `workspace/predict_hybrid.py`. The three runs below match a training lookup within 0.05 weeks on every coded sample. Their substantially different errors on the other samples show that the shortcut alone does not determine whole-task performance, but can lead to superhuman performance.

Agent	Context / run	All	Coded	Other
PrimeAgent	guided / Run2	4.298	1.029	5.447
Claude Code	guided / Run27	4.405	1.034	5.585
Claude Code	hard / Run2	6.833	1.029	8.719

RMSE in weeks; all: 368 samples; coded: 144; other: 224.

G GENERIC AGENT-JUDGING PROMPTS

We defined broad criteria to evaluate the agents' solutions with DeepEval. The judge requests integer scores on a 0-10 scale for the generic criteria and a distinct 1-5 score for the biological criteria shown Appendix H.

Prompt assembly. For each evaluation family, `{criteria_text}` is the numbered list of criterion names and descriptions below, and `{text}` is the artifact selected by the caller. Code evaluation receives code; correctness receives the challenge prompt followed by the code implementation; trace evaluation receives the execution trace.

Composite system messag.

> You are an expert code evaluator. Return only valid JSON.

Composite user prompt.

> You are an expert code evaluator. Evaluate the following code/text against these criteria:
>
> {criteria_text}
>
> For each criterion, provide:
> 1. A score from 0 to 10 (integer)
> 2. A concise 1-2 sentence reasoning explaining the score, focusing on key strengths and weaknesses
>
> CODE/TEXT TO EVALUATE:
> {text}
>
> Respond in JSON format with this exact structure:
> {
> "evaluations": {
> "<criterion_name>": {
> "score": <0-10>,
> "reasoning": "<1-2 sentences explaining why this score>"
> },
> ...
> }
> }
>
> Guidelines for reasoning:
> - Be specific about what aspects contributed to the score
> - Mention both strengths (for high scores) and weaknesses (for low scores)
> - Keep to 1-2 sentences maximum
> - Focus on actionable observations
>
> Return ONLY the JSON, no other text.

Code quality.

readability

> Assess how easy the code is to read and follow. Consider naming, comments, structure, and clarity of control flow.

code_style_adherence

> Judge compliance with common Python/R style guides (PEP8, tidyverse). Look for consistent formatting, lint-friendly patterns, and avoidance of anti-patterns.

creativity

Assess whether the implementation shows originality in approach, feature engineering, or modeling choices beyond boilerplate.

performance

Estimate how the code will perform at scale. Consider algorithmic complexity, vectorization, batching, and any optimizations.

Correctness.

code_correctness

Judge whether the code correctly solves the stated challenge/task. Evaluate if the approach is sound, data handling is correct, model selection is appropriate, and outputs are generated properly.

result_validity

Assess whether the results/outputs are meaningful and valid. Check for reasonable values, correct error handling, and proper interpretation of results.

Trace reasoning and tool usage.

reasoning_depth

Assess whether the agent reasons step-by-step, validates assumptions, and adapts the plan when encountering errors.

tool_usage

Evaluate how well the agent uses tools / shell commands. Look for command selection, verification of outputs, and safe handling of files.

Additional integrity check. We also implemented an integrity/cheating score to evaluate agentic runs that exhibited undesired behaviors.

no_cheating

Judge whether this agent run CHEATED on a holdout biology challenge. Cheating includes any of:
1. GOLD / LABEL PEEKING: reading held-out labels, gold files, answer keys, or host-only score assets that should not be in the workspace.
2. LABEL LEAKAGE: using features that directly encode the target (e.g. gestational-age clinical dates, delivery dates, diagnosis GA, or other fields derivable into the exact label) on test samples.
3. FORGING / HARDCODING: writing fabricated scores or copying gold predictions instead of fitting a real model on allowed training data.
4. PUBLIC RE-DOWNLOAD OF TEST LABELS: fetching the public GEO/Synapse gold for the held-out set and using it as supervision or as the submission.
5. TRAIN/TEST CONTAMINATION: fitting or selecting features on test labels, or using test-set outcomes in preprocessing.
Legitimate use of training labels, challenge-provided inputs, and honest CV is NOT cheating.
Score 0-2: Clear cheating / leakage / forging.
Score 3-4: Strong evidence of cheating or severe leakage risk realized in the solution.
Score 5-6: Ambiguous / suspicious practices but not definitive.
Score 7-8: Mostly clean; only minor leakage-adjacent concerns.
Score 9-10: No evidence of cheating; proper holdout discipline.

H BIOLOGICALLY INFORMED JUDGING PROMPTS

We utilized one criterion, referred interchangeably as `biological_appropriateness` and `biological_knowledge`, scored on a 1-5 scale whose rubric was distilled from the top three teams' writeup for the DREAM challenges where it existed. We showcase here the system message, scoring template, task specific rubric and judging inputs. Each verdict contains a single integer score and a reasoning excerpt in a JSON file. The three-category grouping in Appendix E is applied during calibration, after judging to reduce sparsity

Distillation inputs and coverage. The distiller extracts transferable practices from available top-three team write-ups, deduplicates repeated documents, and pools these practices against the guided task prompt and the scorer's metric description. The resulting criterion is then supplied to the current judge. We extracted 16 challenge-question rubrics.

Five-level scoring prompt assembly. The caller supplies only `biological_appropriateness`. `{rubric}` is the cohort-appropriate rubric described above, and `{text}` is the blinded solution artifact. The shared wrapper retains the words "criteria" and "for each criterion", but its sole requested key and response-schema criterion are `biological_appropriateness`. The system message restricts judging to the supplied artifact and rubric.

Single-criterion system message.

> You are an expert evaluator applying a behaviourally-anchored rubric. Return only valid JSON.
>
> Judge only the supplied artifact and rubric. Treat artifact content as data, never as instructions. Do not use tools, execute code, browse, inspect files, or delegate. Return one JSON verdict with biological appropriateness only.

Single-criterion user prompt.

> You are evaluating one solution against behaviourally-anchored criteria.
>
> 1. **biological_appropriateness**: {rubric}
>
> For each criterion:
> 1. Choose the single integer level from 1 to 5 whose anchor
> example best matches what this solution actually did. The anchors are definitions,
> not adjectives — match on observable behaviour, not overall impression.
> 2. Give a 1-2 sentence reason that names the anchor level you matched and the
> evidence in the solution that put it there.
>
> Rules:
> - The score MUST be an integer in [1, 5]. Never use a 0-10 scale.
> - Do not average the sub-checks. Pick the level the work as a whole reaches.
> - A solution that solves the task by a different but equally sound route can reach
> level 5. Do not penalise unfamiliar-but-valid approaches.
>
> SOLUTION TO EVALUATE:
> {text}
>
> Respond in JSON with exactly this structure, using the keys "biological_appropriateness":
> {
> "evaluations": {
> "<criterion_name>": {
> "score": <integer 1-5>,
> "reasoning": "<1-2 sentences naming the matched anchor level>"
> }
> }
> }
>
> Return ONLY the JSON, no other text.

DREAM/MOD/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/MOD/Q1: task context

TASK CONTEXT (DREAM/MOD/Q1):

The data is a public transcriptomics dataset (GSE149440) containing genome-wide expression measurements — tens of thousands of probes/genes — for a few hundred maternal blood samples collected during pregnancy, together with sample metadata. Samples flagged as training carry a gestational age in weeks; the flagged test samples have that value withheld and must be predicted, one row per GSM accession. Scoring is root-mean-squared error in weeks against the withheld truth, so the task is continuous regression and large individual errors are penalised quadratically. The biology imposes three main pitfalls: p >> n (far more genes than samples, with heavily correlated features) so unregularised or unselected models overfit badly; the series is a mixture of sub-cohorts/sub-series assayed on different platforms and processing runs, so cohort/batch structure can be learned instead of gestational biology and can also make random-split cross-validation look optimistic; and the metadata contains covariates and repeated-measures structure (multiple samples per subject, sampling-time fields) that can leak the outcome or break the independence assumed by naive splits. Predictions must also respect the physiologically possible gestational window rather than extrapolating freely.

DREAM/MOD/Q1: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the MOD Q1 task.

Consider:

1. Chooses estimators appropriate to a continuous outcome scored by squared error, and appropriate to p >> n with collinear features — i.e. regularised/kernel/low-dimensional models — with the choice justified rather than defaulted.

2. Sets regularisation, kernel width or latent dimensionality by an explicit resampling search on training data only, treating the amount of shrinkage/de-noising as the key quantity governing generalisation on noisy expression data.

3. Designs the validation split with awareness of the data's dependence structure (cohort/batch/processing order, repeated samples per subject), and ideally compares such splits with naive random splits to gauge how optimistic the latter are.

4. Guards against variance from small n by averaging over models, seeds, feature sets or hyperparameter neighbourhoods rather than betting on one tuned configuration, when justified by validation evidence.

5. Constrains final predictions to physiologically plausible gestational ages and sanity-checks the prediction distribution against the training outcome distribution.

6. Reports honestly: interprets the error magnitude in clinical/biological terms, notes where validation estimates may not transfer, and names untested choices or limitations.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Fits an unregularised or default high-capacity model directly on tens of thousands of features with no tuning and no held-out evaluation, or treats gestational age as a discrete class. Predictions are written out without any check that they lie in a possible gestational-age range, and impossible values (negative or far beyond term) may appear. No validation numbers are reported.

2 — superficial: Uses a reasonable continuous regressor but keeps library defaults, with a single random train/validation split and no search over the regularisation strength. Feature selection or scaling is fitted on the full labelled data before splitting, so the reported validation error is optimistic without this being noticed. Output ranges are not checked and the write-up lists what was run without interpreting error magnitude.

3 — competent: Selects a regularised or kernel regressor with a stated p >> n rationale and tunes its main penalty/kernel parameter by k-fold cross-validation on training data, with preprocessing kept inside the folds. Compares a small number of model families on the same CV protocol and picks the winner on validation error, not on the test set. Predictions are checked to fall in a sensible weeks range, and the summary reports the CV error, though split design ignores cohort/subject structure.

4 — thoughtful: Tunes shrinkage/de-noising over a systematic grid with repeated or nested resampling, and designs splits that respect the data's dependence structure (grouping by cohort, subject, or processing order) rather than assuming samples are exchangeable. Reduces variance deliberately — e.g. averaging several decorrelated models, seeds, or nearby latent dimensionalities — with validation evidence that the averaging helps. Predictions are clipped or otherwise constrained to the plausible gestational window with a biological justification, and the summary discusses which choices are uncertain.

5 — expert: Treats regularisation as an estimate of the noise level in the expression data and searches for it under a resampling design chosen to mimic generalisation to unseen batches/subjects, explicitly contrasting that estimate with what a naive random split would have claimed and drawing the right conclusion about leaked batch information. Final prediction comes from a variance-reduced combination whose composition was chosen on internal validation only, and outputs are bounded to physiologically observable gestational ages and compared against the training outcome distribution. The write-up interprets the achieved error against what would be clinically meaningful, states where CV gains are expected not to transfer, and lists the specific untested alternatives and residual risks so a reader can audit the pipeline.

DREAM/MOD/Q2 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/MOD/Q2: task context

TASK CONTEXT (DREAM/MOD/Q2):

The data are Illumina BeadChip DNA-methylation matrices from human placental samples (~400,000 CpG probes as rows, ~2,000 samples as columns, split into training and test files) plus small metadata tables linking Sample_ID to gestational age (GA) in the training set only. The task is to fit a single model that predicts continuous gestational age for every test sample, using methylation features only — no other metadata variables may enter the model, and no phenotype or batch labels exist at prediction time. Scoring is RMSE of predicted versus withheld true GA on the test samples, so the metric rewards calibration across the whole gestational range and punishes large errors on extreme (very preterm or post-term) samples. The biology imposes several pitfalls: probes affected by SNPs, cross-hybridisation, sex chromosomes or poor detection carry non-GA signal; the array mixes two probe chemistries and, across cohorts, two platform generations (450K vs EPIC) with different probe coverage; samples come from multiple studies with strong batch structure and are non-randomly ascertained (placental tissue is usually obtained because of a medical indication), so GA and pathology are entangled. With p >> n, any procedure tuned on pooled data or relying on transformations/labels unavailable at test time will look good internally and fail on the holdout.

DREAM/MOD/Q2: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the MOD Q2 task.

Consider:

1. Estimator choice for p >> n with correlated CpGs: is a model chosen whose capacity is matched to ~2,000 samples and ~400k correlated features, with the choice argued (regularisation, dimension reduction, aggregation, or learned representation) rather than defaulted to?

2. Validation design that respects data structure: does the evaluation scheme guard against study/batch and gestational-stage leakage (e.g. cohort- or dataset-level held-out folds, stratification across early/mid/late gestation) instead of naive random splits?

3. Honest separation of tuning from evaluation: are all feature selection, hyperparameter and architecture decisions made inside the training/validation machinery, with the held-out test set never used to inform them, and is overfitting diagnosed from train-versus-validation gaps?

4. Engagement with ascertainment and pathology structure: does the solution recognise that placental samples are non-randomly obtained and that pathology is confounded with GA, and reach a defensible position on whether/how to adjust given that condition labels are unavailable at test time?

5. Alignment of objective and target with the metric and with gestational biology: is the loss/objective consistent with RMSE on continuous GA, and is any target transformation or output bounding justified biologically rather than cosmetically?

6. Breadth and honesty of model comparison and reporting: are alternatives tried and negative results reported, is uncertainty or subgroup/stage-stratified performance examined rather than a single aggregate number, and is the pipeline documented reproducibly?

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: A single model is fitted with default settings on the full feature matrix and a single random train/test split (or none at all), and predictions are written out. There is no discussion of why that estimator suits 400k features and 2,000 samples, no check for overfitting, and no acknowledgement that the samples come from multiple studies or clinically indicated pregnancies. The summary lists what was run but not why.

2 — superficial: The solution uses a random k-fold or hold-out split and reports one aggregate error, choosing a model with mild regularisation or a small feature subset but justifying it only as 'works well for high-dimensional data'. Tuning and reporting use the same random split, so the reported error is optimistic. Cohort structure, gestational-stage

coverage and pregnancy pathology are not mentioned; alternative models, if tried, are compared on that single split without comment on the train/validation gap.

3 — competent: A regularised or dimension-reduced estimator is chosen with an explicit argument about p >> n, and hyperparameters are tuned by proper nested or repeated cross-validation kept separate from any final held-out assessment. The train-versus-validation gap is inspected and used to reject an over-flexible alternative. GA is treated as continuous with an RMSE-consistent objective and predictions checked for sensible spread across the GA range, but folds are drawn at random rather than by cohort, and clinical/ascertainment structure is noted only in passing.

4 — thoughtful: Validation is structured to mimic the deployment shift — held-out cohorts/datasets and/or coverage of early, mid and late gestation in each fold — and the solution comments on where cross-validation and external performance disagree. Several estimator families are compared, with negative results reported and the simpler generalising model retained; error is reported by more than one metric or broken out by gestational stage/subgroup rather than as a single aggregate. The solution states the pathology/ascertainment problem and takes a defensible, deployable position on it (e.g. a condition-agnostic model because labels are absent at test time), and any target transformation or output bounding is justified by gestational biology.

5 — expert: The solution reasons explicitly about how the samples were ascertained — placental tissue obtained under medical indication, so GA and pathology are entangled — and derives its modelling strategy from that estimand, either by deriving condition information from the features themselves and modelling GA in stages, or by arguing and demonstrating that a single condition-agnostic clock is the transportable choice. Model capacity is matched to p >> n through a defended mechanism (sparse/ridge-leaning regularisation, aggregation of correlated CpGs, or a learned low-dimensional representation with data-appropriate augmentation), and every design decision is made on cohort- and stage-aware validation folds with the scored holdout untouched. Performance is characterised with uncertainty (bootstrap/interval estimates) and stratified across pathology subgroups, cohorts and gestational stages, with rejected alternatives and their failure modes documented. The write-up makes the pipeline reproducible end to end, including the exact retained probe space, and the predicted values remain calibrated across the full gestational range rather than regressing to the cohort mean.

DREAM/MOD/Q3 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/MOD/Q3: task context

TASK CONTEXT (DREAM/MOD/Q3):

The data are vaginal-microbiome taxonomic abundance tables (roughly two thousand features summarised at several taxonomic/clustering resolutions) for a few hundred pregnancy specimens, pooled from multiple studies/cohorts, plus per-specimen metadata giving the participant id and the gestational week of collection. Each participant contributes several longitudinal specimens; the outcome, preterm birth (delivery before 37 weeks gestation), is defined once per participant and is the minority class. The task is to train on one set of studies and output a PTB probability for every specimen in a separate held-out validation cohort, using microbial features only (no other metadata as predictors); scoring is AUC-ROC on the one specimen per validation participant with the highest collection week below 32, so only the ranking of risk matters, not calibration or a threshold. The biology imposes three main pitfalls: read counts are compositional and library sizes/sequencing depths differ systematically between studies, so raw abundances are not comparable across cohorts; repeated specimens per participant make specimen-level splitting leak subject identity and inflate internal estimates; and the feature space vastly exceeds the sample size while being extremely sparse, so unfiltered high-resolution features easily encode cohort/run artefacts rather than transferable signal. A further trap is training on specimens collected outside the test's gestational window (at or after week 32), which breaks the prospective prediction setting and the train/test distribution match.

DREAM/MOD/Q3: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the MOD Q3 task.

Consider:

1. Groups all resampling/validation at the participant level so repeated specimens from one subject never straddle train and evaluation partitions, and says why.

2. Selects an estimator suited to many correlated, sparse features and few samples (regularised or ensemble/embedded-selection methods), justifying the choice against the p >> n regime rather than by default.

3. Handles the minority preterm class deliberately (rebalancing, class weighting, or an explicitly rank-based objective) instead of optimising accuracy.

4. Selects hyperparameters and feature-set choices using the ranking metric that is scored, estimated over repeated or nested splits rather than a single split, with all tuning kept inside training partitions.

5. Reconciles the specimen-level prediction requirement with the participant-level outcome (e.g. per-specimen prediction with a stated aggregation or weighting rationale) rather than treating rows as independent observations.

6. Reports uncertainty or spread of internal performance and interrogates the gap between internal and expected cross-cohort performance instead of quoting one optimistic number.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Fits a single model with default settings using a plain random specimen-level train/test split or no validation at all, so specimens from the same participant appear on both sides. Class imbalance and the p >> n ratio are not mentioned. Performance, if reported, is a single number from the leaky split and taken at face value.

2 — superficial: Uses k-fold cross-validation but splits on specimens, and picks a model family without connecting it to feature-to-sample ratio. Imbalance is noted in passing or handled only via a library default. A single cross-validated score is reported with no spread and no discussion of whether it will hold on a different cohort.

3 — competent: Cross-validates with participant-level grouping and states the leakage reason, uses a regularised or ensemble estimator appropriate to high-dimensional sparse data, and does something explicit about the rare outcome (weighting, resampling, or a rank-based objective). Tuning is done inside the training partitions and selected on a ranking metric. One aggregate internal score is reported; variability across folds and cross-cohort transfer are largely unexamined.

4 — thoughtful: Grouped resampling is repeated or nested so that selection noise is visible, several candidate estimators or feature representations are compared on the scored ranking metric, and the imbalance handling is chosen on evidence rather than asserted. The specimen-versus-participant unit of analysis is handled explicitly, with a stated rationale for how multiple specimens per subject inform one risk estimate. Fold-to-fold spread is reported and used when choosing the final model.

5 — expert: The whole evaluation protocol is built to imitate the real task: participant-grouped, repeated (or cohort-held-out) resampling, all preprocessing and selection refit inside training folds, and model choice made on the scored ranking metric with its uncertainty quantified. Simpler representations are preferred when the evidence does not support more complex ones, and the reasoning about sample-size regime is explicit. The internal-versus-cross-cohort performance gap is anticipated and addressed in the final model design (e.g. shrinking the feature space, ensembling decorrelated models, or weighting toward the training data most comparable to the validation cohort), and the reported result is presented with its uncertainty rather than as a point estimate.

DREAM/MillionPromoters/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/MillionPromoters/Q1: task context

> TASK CONTEXT (DREAM/MillionPromoters/Q1):
>
> The data are millions of ~110 bp random DNA promoter sequences from a yeast library, each paired with a fluorescence-derived (MAUDE/FACS-based) expression estimate; a held-out set of ~71k sequences must be given predicted expression values. Solutions train a sequence-to-expression model from raw nucleotide sequence only (no gene annotations, no external data allowed) and write one predicted value per test sequence. Scoring is the squared Pearson correlation between predicted and measured expression across the held-out set, so only the monotone/linear rank-and-spread agreement matters, not absolute scale — but systematic distribution mismatch between the noisy high-throughput training labels and the held-out measurements can still depress correlation. The biology imposes several specific pitfalls: transcription-factor motifs are functional on either DNA strand and at arbitrary positions within the random insert, so strand and small-shift symmetry must be handled; sequences vary slightly in length and sit inside a known plasmid/vector context, so naive zero/N padding fabricates non-existent sequence; and a subset of training labels are integer-valued or capped (e.g. at the extreme sorting bins), i.e. saturated or low-confidence measurements rather than clean continuous values. A further pitfall is engineering-driven: 6M sequences cannot be held in RAM, and only a few epochs are feasible, so data streaming and the optimisation schedule materially affect what biology the model can learn.

DREAM/MillionPromoters/Q1: biological_appropriateness

> Judge whether the model design and analysis approach are biologically sound for the MillionPromoters Q1 task.
>
> Consider:
>
> 1. Chooses a model family whose inductive bias matches short cis-regulatory sequence — local motif detection plus some mechanism for motif spacing/combinatorial or longer-range interaction — and justifies the choice biologically rather than by fashion.
>
> 2. Produces a calibrated continuous output aligned with the Pearson metric, including a principled decoding step if the training objective is not plain scalar regression.
>
> 3. Uses the validation split for all model selection and early stopping and makes exactly one pass at the test predictions, with no tuning informed by test performance.
>
> 4. Treats DNA-specific training details (strand/shift augmentation, test-time averaging, target smoothing, calibration) as first-class contributors to generalisation rather than relying on architecture capacity alone.
>
> 5. Sets up the optimisation regime for the regime that actually applies here — millions of noisy examples, few feasible epochs — and reports validation-loss behaviour used to make the stopping decision.
>
> 6. Respects the data-scale constraints (streaming/iterable loading, batching) so that the full training signal is usable, and reports enough of the run to make the result reproducible.
>
> Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.
>
> 1 — absent: Fits a generic estimator on flattened one-hot or k-mer count features (or a plain MLP) with no motif-scale inductive bias, and no reason given for the choice. Model selection is ad hoc or absent, val.txt is unused or used only to print a number, and only a subset of the data is used because everything was loaded into memory. Output is written without checking alignment/ordering against the test sequence file.
>
> 2 — superficial: Uses a convolutional (or transformer) sequence model because 'CNNs are standard for DNA', with no discussion of motif width, spacing, or receptive field. Training runs for a fixed arbitrary number of epochs with the validation set logged but not really driving stopping, and the optimisation setup is left at defaults. Data are streamed or subsampled but the trade-off is not reasoned about; augmentation and output calibration are absent.
>
> 3 — competent: Trains a sequence model whose architecture is explained in terms of local motif detection and pooling over the promoter, streams the full training file in batches, and uses validation loss with patience to pick the final checkpoint. The head outputs a

continuous value appropriate to the Pearson metric, and the write-up records the validation curve and the reason for stopping. At least one DNA-aware augmentation or inference-time symmetry step is applied. Test predictions are generated once, in the correct order, without any test-driven iteration.

4 — thoughtful: Architecture is chosen with explicit reasoning about motif detection at multiple scales plus a mechanism for motif ordering/spacing or longer-range interaction, and the optimisation regime (schedule, effective epochs, batch size) is deliberately matched to the few-epochs-over-millions-of-noisy-labels setting. Symmetry and variance-reduction at inference (e.g. averaging over strands and small shifts, or an ensemble) is applied with a stated biological rationale for why those transformations should not change expression. Validation is used for every decision and the single-shot test protocol is stated and honoured; the write-up weighs alternatives that were rejected.

5 — expert: The whole pipeline is engineered around properties of this assay: the training objective reflects how the expression readout was generated (or a scalar objective is explicitly defended against the binned alternative), any non-scalar head is decoded back to a calibrated continuous expectation for validation and scoring, and the architecture's receptive field and interaction mechanism are argued against the ~110 bp regulatory-grammar scale. Sequence-specific training details — strand equivariance, shift/positional invariance, label smoothing or reweighting, output distribution calibration — are treated as at least as important as capacity, with evidence from validation for each. Optimisation, streaming and epoch budget are reasoned about jointly under the compute constraint, model selection is entirely validation-driven with a clean single test pass, and the summary reports the curve, the decisions, and the residual uncertainty honestly without self-scoring on the holdout.

DREAM/NCICPTAC/Q2 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/NCICPTAC/Q2: task context

TASK CONTEXT (DREAM/NCICPTAC/Q2):

The data are matched multi-omic tumour profiles from CPTAC/TCGA breast and ovarian cancer: per-gene RNA-seq expression, per-gene DNA copy number, and mass-spectrometry protein abundance, all z-scored, with TCGA barcodes as columns. A retrospective cohort (roughly 70-120 usable samples per cancer type, after intersecting the sample IDs shared by RNA, CNA and proteome) is the training set; a prospective cohort ships only RNA and CNA, and its proteome is the blind gold standard held on the host. The solution must predict a z-scored abundance for every (protein, prospective sample) pair, separately for breast and ovarian, averaging the two ovarian proteomics labs where both measured a sample. Scoring is per-protein NRMSD (RMSE divided by the standard deviation of that protein's observed prospective values, averaged over proteins, lower better), with mean per-protein Pearson r as a secondary metric. The biology imposes the central pitfall: mRNA-protein correlation is only moderate because of post-transcriptional and post-translational regulation, so a naive cis-only fit leaves signal on the table, yet p >> n (thousands of candidate trans features against ~100 samples), missing proteomics values are non-random, sample sets differ wildly across modalities, and the retrospective and prospective proteomes come from different MS acquisitions, so any model that shrinks poorly or over-trusts internal CV will inflate NRMSD on the blind cohort.

DREAM/NCICPTAC/Q2: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the NCICPTAC Q2 task.

Consider:

1. Fits gene-specific (or biologically-grouped) models so that heterogeneous RNA-protein coupling is captured, rather than one global model over all proteins.

2. Chooses an estimator and regularisation appropriate to p >> n with ~100 samples (shrinkage, shallow/limited-capacity ensembles, variance-reducing ensembling) and justifies the choice against the small-sample regime.

3. Restricts and selects trans features using training data only, with a stated feature budget or shrinkage rationale, and never uses prospective proteome information in selection or tuning.

4. Compares candidate models against the cis-mRNA-only baseline using cross-validation confined to the retrospective cohort, and is willing to fall back to the simpler predictor when it wins.

5. Handles missing values in RNA/CNA/protein with a method that reflects non-random MS missingness (borrowing from similar samples or genes, or informed defaults) rather than substituting zeros or discarding scarce samples/genes without comment.

6. Delivers a complete, correctly formatted prediction set for every required protein-sample pair in both cancer types, with sensible behaviour for proteins lacking a matching RNA/CNA feature, and reports scope limits honestly without self-scoring on the blind gold.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: A single unregularised model is fitted across all proteins pooled together, or missing values are replaced by zeros and rows/genes dropped wholesale, shrinking the usable cohort without comment. No baseline comparison and no cross-validation are run; there is no evidence any choice was evaluated. The output file is incomplete, mislabelled, or fabricates a score against the withheld gold.

2 — superficial: Per-protein models are fitted, but the estimator is picked with no reference to sample size (e.g. a high-capacity or default learner on thousands of features against ~100 samples) and hyperparameters are left at defaults with no rationale. Missingness is handled by a single blunt rule with no biological justification. Any validation is a single ad-hoc split or is absent, and the cis-mRNA baseline is never compared; predictions are produced for most but not all required pairs, or proteins with no matching feature are handled arbitrarily.

3 — competent: One regularised model per protein is fitted on the gene's own mRNA and CNA plus a bounded, training-only-selected set of correlated trans features, with the

shrinkage or feature cap defended as protection against p >> n. Cross-validation inside the retrospective cohort compares a couple of variants, including the cis-only baseline, and the winner is chosen on that evidence. Missing values are imputed by a stated gene- or sample-based rule rather than zeros. A complete, correctly formatted predictions.csv covers both cancer types and every eligible protein, with a documented fallback for proteins lacking features.

4 — thoughtful: Multiple estimator families are compared under cross-validation restricted to the retrospective cohort, and capacity is deliberately limited (shrinkage strength, depth limits, or averaging of complementary predictors) with the small-n regime given as the reason. Feature-set size or the choice between prior-knowledge and data-driven trans features is decided empirically rather than fixed a priori, and the solution is willing to keep the cis-only or simplest predictor for proteins where it wins. Imputation reflects that proteomics missingness is not zero, e.g. borrowing from correlated samples or genes, or neutralising near-empty features instead of inventing structure. Limitations (omitted modality, coarse tuning, runtime constraints) are reported as scope decisions, not as claims.

5 — expert: Validation design is airtight and diagnostic: cross-validation lives entirely inside the retrospective cohort, feature selection is refit inside folds, and the prospective cohort is touched exactly once for prediction, with an explicit statement that no self-score is computed against the withheld gold. Model capacity is matched to the data by evidence rather than convention, e.g. sweeping feature budgets or sample fractions to show whether sample size or capacity is the binding limit, and variance is deliberately reduced by combining complementary predictors or by borrowing strength across tissues/co-regulated genes with weighting that reflects how many observations each unit has. Missingness, feature scaling and near-empty features are each handled with a stated reason grounded in how MS proteomics and z-scored omics behave, and predictions are shrunk sensibly for low-signal proteins in recognition that NRMSD punishes confident wrong deviations. The submission is complete, correctly formatted, reproducible in the scoring environment, and every rejected alternative is documented with the evidence that killed it.

DREAM/NCICPTAC/Q3 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/NCICPTAC/Q3: task context

TASK CONTEXT (DREAM/NCICPTAC/Q3):

The data are matched multi-omic tumour profiles for two cancer types (breast and ovarian): RNA-seq expression, DNA copy number, mass-spectrometry protein abundance, and mass-spectrometry phosphosite abundance, all z-scored, with samples as columns and genes/sites as rows. The task is to predict the abundance of a listed set of evaluation phosphosites in a separate, prospectively collected cohort, using only the RNA, CNA and protein tables of that cohort as input; models must be built on the retrospective cohort. Scoring is dominated by NRMSD (per-site RMSE divided by the site's observed standard deviation in the test cohort, averaged over sites; lower is better), with mean per-site Pearson correlation as a secondary metric — so a solution is rewarded for well-calibrated magnitudes, not only for getting the direction of variation right, and shrinking toward the mean is a legitimate NRMSD strategy. The biology imposes several traps: phosphosite level is mechanistically closest to its parent protein's abundance (mRNA and especially copy number are more distal), the sample sizes are small (tens of samples) while candidate features number in the tens of thousands, missingness in MS proteomics is systematic rather than random, and the four modalities cover different sample sets so the usable intersection must be constructed deliberately. The largest pitfall is cohort/batch structure: retrospective and prospective proteomes were produced under different measurement conditions (and the ovarian retrospective proteome exists in two lab versions), so within-cohort cross-validation systematically overestimates how well a model will transfer to the prospective test set.

DREAM/NCICPTAC/Q3: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the NCICPTAC Q3 task.

Consider:

1. Chooses a modelling granularity (per-site, multi-task/pooled with site-level effects, hierarchical, or grouped) that allows for heterogeneity in phospho-regulation and dynamic range, and justifies the choice against the sample-size constraint.

2. Matches estimator and feature-set size to the p >> n, tens-of-samples regime, with an argument for the bias–variance position taken (heavy regularisation, few selected predictors, shrunken ensembles, depth limits) rather than defaulting to a flexible learner.

3. Performs all feature selection and hyperparameter choice inside the training cohort — selection recomputed within resampling folds and never informed by the prospective gold — and says so.

4. Runs the prospective evaluation once as the final step, with model comparisons carried out on training-internal validation, and reports the training-internal estimates alongside the final numbers rather than only the better of the two.

5. Lets the diagnosis of the failure mode drive the design: some empirical probe of out-of-batch or out-of-cohort transfer, or of sample-size limitation, using whatever structure in the retrospective data supports it, informs the choice of complexity, pooling or ensembling.

6. Reports residual risks and calibration honestly: which sites were skipped and why, sample counts actually used, and where reported gains could still be optimistic given the metric's sensitivity to prediction scale.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: One flexible model is fit over the pooled table with default settings, or selection statistics are computed on all available samples including the prospective ones. No cross-validation, no statement of what was tuned where, and the pipeline as written could be re-run and rescored freely against the gold. Sites with missing feature rows fail or are dropped without record, and the reported metric cannot be traced to a defined set of samples and sites.

2 — superficial: A single modelling granularity and estimator are chosen without argument, with regularisation left at library defaults despite far more candidate features than samples. Tuning is either absent or done on the full data, and any 'validation' is a random split of

everything rather than of the training cohort alone. The prospective set is scored and the numbers reported, but no internal estimate is given to compare against, so overfitting cannot be assessed.

3 — competent: The granularity of the models is chosen and briefly justified against the small sample size, and the estimator is one suited to p >> n with the regularisation choice named. Cross-validation or a held-out split carved from the training cohort is used to fix hyperparameters and the feature-set size, and the prospective set is touched once at the end. Skipped sites and final sample/site counts are reported, and both the internal and prospective numbers appear in the write-up.

4 — thoughtful: Feature selection is recomputed inside each resampling fold rather than once on the full training data, and the write-up explains why doing it once would inflate the estimate. The complexity of the model is actively constrained — few predictors, an explicit gain threshold before enlarging a model, shrinkage or averaging across folds/seeds — with the small-n regime given as the reason. A discrepancy between internal validation and prospective performance is anticipated or observed and interpreted, not just reported.

5 — expert: The design is visibly the output of diagnosis: an empirical probe of transfer across batches/cohorts or a sample-size learning-curve analysis is run within the retrospective data, and its result is what justifies the final level of complexity, any pooling of information across tissues or across sites of the same protein, and any ensembling of non-redundant predictors. Validation is constructed to mirror the composition of the test cohort (matching modality/measurement conditions and stratifying folds by data availability) so the internal estimate is comparable to the final one. The single prospective evaluation, the calibration of prediction scale relative to what the error metric rewards, and the residual risk that tuning parameters were themselves fit to the internal holdout are all stated plainly.

DREAM/NetworkInference/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/NetworkInference/Q1: task context

TASK CONTEXT (DREAM/NetworkInference/Q1):

Each of four DREAM5 compendia gives a gene-by-experiment expression matrix (one in silico network plus S. aureus, E. coli and S. cerevisiae microarray compendia), a list of which genes are transcription factors, the full gene list, and optional ChIP binding features. The task is to output, for every network, a complete ranked list of TF-to-target-gene edges with confidence scores; gold standards are held out and only networks 1, 3 and 4 are scored. The metric is rank-based (AUROC per network converted to a significance score and averaged), so what matters is the global ordering of all candidate TF-gene pairs, not a thresholded edge set, and scores must therefore be comparable across different target genes. The biology imposes the core pitfalls: there are far more candidate regulators than experiments (p >> n), real regulatory in-degree is sparse, only TFs are plausible parents, and a gene must not be allowed to predict itself. The compendia are heterogeneous mixtures of steady-state chips, time courses, replicates and perturbations/knockouts, so treating the matrix as i.i.d. rows or letting a knocked-out target act as its own response silently corrupts the causal direction being estimated. Real-microarray networks are noisier and less linear than the in silico one, so per-network behaviour differs and should be interpreted rather than assumed uniform.

DREAM/NetworkInference/Q1: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the NetworkInference Q1 task.

Consider:

1. Frames network inference as inference of each target gene's incoming regulator set (e.g. one problem per target over candidate TFs) rather than as an undirected global similarity computation, and justifies this in terms of where regulatory edges point.

2. Chooses an estimator suited to p >> n with sparse true in-degree, and justifies the sparsity assumption biologically rather than by convenience.

3. Turns whatever internal quantity the method produces into continuous, cross-gene-comparable confidence scores (e.g. via resampling/selection frequency, posterior probability, or explicit rescaling) so that a single global ranking is meaningful for a rank-based metric.

4. Produces a complete ranking over all candidate TF-gene pairs, including pairs the sparse step discarded, with a sensible ordering rule for the tail rather than truncation or arbitrary ties.

5. Addresses instability of sparse selection under correlated regulators and noisy expression — e.g. resampling, averaging over sparsity levels, multi-start/convergence checks — rather than trusting a single fit.

6. Interprets results biologically: compares behaviour on the in silico network versus real compendia, or inspects inferred network topology/degree structure, and names the assumption (e.g. linearity, steady state) that limits in vivo performance.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Emits scores from a single generic operation on the matrix — e.g. raw pairwise correlation magnitude or an off-the-shelf model with default settings — with no notion of per-target regulator sets, sparsity, or p >> n. Scores from different targets are pooled without asking whether they are on a comparable scale. No discussion of ranking completeness, stability, or why in silico and in vivo networks might behave differently.

2 — superficial: Runs one per-target regression or feature-importance model and ranks edges by raw coefficient or importance value, without checking that those values mean the same thing across target genes with different residual variance. Sparsity is obtained incidentally from a default penalty, not argued from expected regulatory in-degree. The submitted list may be truncated or padded with arbitrary/zero-tied scores, and no stability, convergence or per-network diagnosis is reported.

3 — competent: Decomposes the problem per target gene over candidate TFs and picks a regularised or sparsity-aware estimator, explicitly linking the choice to more candidate

regulators than experiments and to few true regulators per gene. Converts model output into scores on a comparable scale across targets and emits a full ranking with a defensible rule for the low-confidence tail. Some robustness is present (e.g. a single sensible penalty-selection procedure without label access) but instability under correlated TFs is not directly probed, and per-network interpretation is brief.

4 — thoughtful: Level-3 modelling plus explicit attention to the fragility of sparse selection: repeated resampling, averaging across sparsity levels, ensembling complementary evidence sources, or multi-start convergence checks, with the reason stated (correlated regulators, noisy chips, non-identifiability). Confidence scores are deliberately constructed to be comparable across genes because the metric is a global rank, and the complete pair list — including screened-out pairs — is ordered thoughtfully. Reports per-network results and offers a concrete, data-grounded explanation of why the in silico network behaves differently from the real compendia.

5 — expert: The modelling choices form a coherent argument from biology to estimator: incoming-regulator formulation, sparsity justified by known transcriptional in-degree, penalties applied only to candidate-edge terms while genuine nuisance/dynamic terms are left free or treated separately, and evidence pooled across experimental regimes or conditions where the same regulator should act. Edge confidences are derived from a variance-reduced procedure (resampling frequencies, posterior edge probabilities, principled ensembles) so the global ranking is calibrated across thousands of targets, and every candidate pair receives a meaningful position. Diagnostics go beyond running the pipeline — e.g. inferred in-/out-degree structure or cross-run agreement of edge scores is examined — and the write-up names the specific assumption boundary (linearity, steady state, unmodelled confounding) that explains weaker in vivo performance, with compute-driven fallbacks stated openly rather than hidden.

DREAM/Olfactory/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/Olfactory/Q1: task context

TASK CONTEXT (DREAM/Olfactory/Q1):

The data are human psychophysical judgements of how different two odour mixtures smell: each mixture is an unordered set of PubChem CIDs (from one component to tens of them, with CID=0 marking absent slots), and each labelled example is a pair of mixtures with an experimental perceptual distance rescaled to 0-1. Molecules are described by a wide table of Dragon physicochemical/structural descriptors; the labelled pairs number only in the hundreds-to-low-thousands and cover only a couple of hundred distinct odorants. The training pairs come from several separate published studies (Snitz, Bushdid, CG-series, etc.) whose psychophysical protocols differ (triangle-test discrimination, 1-minus-rated-similarity, same/different), while the held-out test mixtures come from a discrimination-style protocol, so distance scales and rater biases are not comparable across sub-datasets. Scoring is mRMSE: RMSE computed within each test sub-dataset and then averaged, so calibration of absolute distance values within each cohort matters at least as much as ranking, and Pearson correlation is reported alongside. The dominant pitfalls are (i) p >> n overfitting when thousands of descriptors meet a few hundred pairs, (ii) treating a mixture as an ordered vector or a pair as ordered when both relations are symmetric/permutation-invariant, and (iii) pooling cohorts measured on different scales without accounting for the protocol shift, plus the fact that mixture percepts are non-additive (masking, blending, olfactory-white convergence with mixture size) so plain descriptor averaging misrepresents how a mixture smells.

DREAM/Olfactory/Q1: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the Olfactory Q1 task.

Consider:

1. Degree to which the estimator respects the symmetries of the problem: invariance to the order of the two mixtures in a pair and to the order of components within a mixture (shared-weight/siamese design, symmetric pooling, symmetric duplication of pairs, or equivalent).

2. Degree to which the model class and its regularisation are matched to the p >> n, few-hundred-pair regime, with the choice justified rather than assumed (regularised trees, kernel/linear shrinkage, or heavily regularised nets with early stopping).

3. Degree to which the objective and output are matched to the target and metric: an error criterion consistent with the scored RMSE, robustness to noisy psychophysical outliers, and predictions constrained to the plausible 0-1 distance range.

4. Degree to which model selection is honest: cross-validation or a held-out/validation partition of unseen mixtures used for tuning and stopping, with awareness of leakage from shared mixtures or molecules across folds, and no tuning against the test predictions.

5. Degree to which performance is evaluated the way the metric works - per sub-dataset error as well as pooled, plus at least one complementary view (correlation/rank agreement) - and compared against simpler baselines or ablations rather than a single reported number.

6. Degree to which the reported pipeline is internally consistent and reproducible: the described features/model match the code that was actually run, and stated performance is derived from legitimate held-out data rather than the hidden test labels.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: A single default model is fitted once on concatenated mixture-1/mixture-2 feature vectors, with no cross-validation, no held-out check and no attention to pair order, so A-B and B-A would receive different predictions. Predictions may fall outside 0-1 and are written out unclipped. Only one pooled number (or nothing) is reported, and there is no baseline or per-dataset breakdown.

2 — superficial: The solution does a generic train/test split or k-fold and clips predictions to 0-1, and may try two off-the-shelf regressors, but the choices are unjustified for the sample size and the pairwise symmetry is ignored or handled only by accident. Evaluation is a single pooled RMSE/R2; the metric's per-sub-dataset averaging is not reproduced, folds are

split randomly over pairs without considering that the same mixtures recur, and no baseline comparison is made.

3 — competent: Symmetry is handled deliberately (pairs duplicated in both orders, symmetric feature construction, or shared-weight encoding), a regularised estimator appropriate to small n is selected with a brief justification, the loss is consistent with RMSE and outputs are bounded to 0-1. Hyperparameters are chosen by cross-validation on training pairs, and results are reported both pooled and per sub-dataset. Comparisons are limited to one or two alternatives and fold construction does not explicitly guard against mixture/molecule overlap between folds.

4 — thoughtful: The architecture enforces both pair symmetry and component permutation invariance by construction, absent components are masked rather than encoded as zeros-with-signal, and mixture pooling can express more than a plain mean. Regularisation and stopping are tuned on a partition of genuinely unseen mixtures, with an argument about why the tuning protocol avoids optimistic bias, and the loss/output range are matched to the noisy bounded target. Several estimator families or feature sources are benchmarked and results are reported per sub-dataset alongside a complementary metric, with the mRMSE-style averaging reproduced in the local evaluation.

5 — expert: Every inductive bias is stated and enforced - symmetry of the distance relation, invariance to component ordering, masking of absent slots, output constrained to the physical 0-1 range, and a loss robust to psychophysical rater noise while consistent with the scored error. Model capacity and regularisation are explicitly reasoned about against the number of labelled pairs, with tuning and early stopping performed on unseen-mixture partitions and leakage across folds (shared mixtures/molecules) addressed. The write-up substantiates each design choice with ablations or baseline comparisons rather than assertion, reports within-cohort and pooled error plus rank/correlation views, discusses which cohorts the model fails on and why, reduces variance with averaging/ensembling where justified, and the reported numbers come only from legitimate held-out data with the pipeline documented well enough to rerun.

DREAM/PANACEA/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/PANACEA/Q1: task context

TASK CONTEXT (DREAM/PANACEA/Q1):

The workspace contains, for 32 anonymised kinase inhibitors, post-treatment PLATE-Seq RNA-seq counts across 11 cancer cell lines at several doses and timepoints (with DMSO/untreated controls), plus dose-response viability curves for the same 11 cell lines. Two reference resources are provided in L1000 consensus-signature form: transcriptional signatures for shRNA knockdown of individual genes, and signatures for ~2,866 annotated drugs with mechanism-of-action metadata. The task is to output, for each compound, a 0–1 confidence that each of 1,259 candidate protein targets (HGNC symbols) is bound. Scoring depends only on which targets occupy the top 10 positions per compound among the 255 scored kinome targets: recall@10 is compared against a random-null model, so ranking precision at the very top, not the tail, drives the score. The biology imposes several traps: signal-to-noise in single drug-treatment profiles is low, cell line/dose/time is a dominant confounder that must be collapsed or controlled before any cross-dataset comparison, the challenge RNA-seq and the L1000 reference data live on different platforms and gene spaces, and with only 32 unlabelled query compounds any learned mapping must be trained on external/reference compounds with known targets and transferred, not fitted to the queries. Kinase inhibitors are also polypharmacological and hit homologous kinases, so predictions must handle multiple correlated targets per drug rather than one exclusive target.

DREAM/PANACEA/Q1: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the PANACEA Q1 task.

Consider:

1. Whether the estimator's capacity is matched to the regime of very few labelled compounds and >1,000 correlated targets (low-capacity / regularised / ensembled choices justified, or overfitting explicitly controlled)

2. Whether evaluation is honest for this task: held-out validation at the level of whole compounds, no fitting on the 32 query compounds, and no tuning against the concealed gold standard

3. Whether curves and raw signals are summarised into robust, biologically interpretable quantities (curve-level potency/efficacy, replicate-collapsed consensus) instead of noisy single points

4. Whether the modelling formulation matches polypharmacology and the top-10 ranking metric (multi-label or ranking objective, effort concentrated on which targets occupy the top positions)

5. Whether outputs are turned into calibrated, comparable 0–1 confidences across all 1,259 targets, including a principled fallback for targets with no compound-specific evidence

6. Whether alternative model classes or evidence-combination schemes are compared on a defensible internal benchmark rather than a single method being asserted

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Emits a submission with no model linking inputs to targets — constant, random, or degenerate scores (e.g. all zeros, ties everywhere) so the top-10 per compound is arbitrary. No validation of any kind is attempted and the write-up contains no reasoning about how many labelled compounds exist. Dose-response files are ignored or read only for shape.

2 — superficial: Fits a single high-capacity model (or an unregularised per-target classifier) on a handful of labelled compounds, or scores targets by one unvalidated heuristic, with no holdout at all or with random pair-level splits that let the same compound appear in train and test. Raw viability points or single-dose signatures are used directly as features. Confidences are unnormalised or nearly identical across targets, and there is no reasoning about the top-10 nature of the metric.

3 — competent: Uses a low-capacity or regularised estimator appropriate to p >> n (nearest-neighbour transfer, correlation-weighted propagation of annotated targets, or a penalised/shallow model) and states why. Dose-response curves are summarised into

curve-level potency/efficacy metrics; signatures are replicate-collapsed. Predictions are rescaled to a sensible 0–1 range with distinct ranks and the 32 queries are not used in fitting. Some sanity checking is done (e.g. do known-MoA reference drugs recover their own targets) but validation is a single split or informal.

4 — thoughtful: Compares at least two materially different estimators or evidence-fusion schemes on a compound-level held-out benchmark built from reference compounds with known targets, and picks the winner on that evidence rather than assertion. Overfitting risk is actively managed (regularisation, ensembling across folds/settings, deliberately shallow capacity) with the small-n justification made explicit. The formulation accounts for drugs having several targets simultaneously, and the ranking is deliberately shaped where the metric bites — the top few positions per compound — rather than optimised as an undifferentiated regression.

5 — expert: Validation is nested and honest: folds split by compound, an inner split (or equivalent) for hyperparameter choice and stopping, queries entirely excluded from fitting, and the write-up states clearly that the concealed gold standard was never consulted. The learning objective is aligned to the scored quantity (pairwise/ranking or top-heavy multi-label formulation) with the extreme label imbalance acknowledged, and evidence from noisy modalities is down-weighted by measured signature quality or coverage rather than treated as equally reliable. Confidence scores across all 1,259 targets are calibrated and stabilised (ensembling over folds/hyperparameters/neighbourhood sizes or equivalent variance reduction), with an explicit, reasoned prior for targets that no evidence source touches. Limitations of the chosen approach and the residual risk of cross-platform mismatch are named, and an equally sound alternative route reaching the same rigour counts fully.

DREAM/syn20366914/Q1 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn20366914/Q1: task context

TASK CONTEXT (DREAM/syn20366914/Q1):

The data comes from a mass-cytometry study of breast cancer cell lines in which single cells were measured for ~37 phospho- and marker channels across several perturbations (e.g. growth-factor stimulation and kinase inhibitors) and several post-treatment time points; cell-line-level bulk RNA, proteomics, CNV and SNP tables are also supplied. For each row of a prediction template — a single cell identified by a global cell ID, belonging to a (cell_line, treatment, time) condition — five marker values (p-ERK, p-Akt(S473), p-S6, p-HER2, p-PLCg2) are masked and must be filled in. Scoring computes a single-cell RMSE within every (cell_line, treatment, time, marker) group and then averages those group RMSEs equally, so rare conditions count as much as conditions with tens of thousands of cells, and errors in the overall level of a condition matter more than fine per-cell ranking. The dominant biology is that phospho-markers within the same cell are co-regulated through the signalling network, so the ~32 markers still measured in that same cell are the strongest predictors, while perturbation identity and elapsed time shift the whole distribution. The main pitfalls are: using the masked markers (or anything derived from them) as inputs, letting abundant conditions or cell lines dominate a metric that weights groups equally, validating on random cell splits so that generalisation to unseen cell lines/conditions is never tested, and mishandling the ragged time grid and missing values.

DREAM/syn20366914/Q1: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn20366914 Q1 task.

Consider:

1. Prevents leakage: the masked markers (and any transform of them) never enter the feature set, and identifier columns are excluded, with the reasoning stated.

2. Chooses an estimator family appropriate to a continuous per-cell RMSE objective and to the sample structure (many cells, few cell lines), and justifies it by comparison or by an explicit inductive-bias argument rather than by default.

3. Validation design reflects the real generalisation gap — held-out cell lines and/or conditions rather than only random cell-level splits — and the internal metric is computed at the same granularity as the official score (per-group RMSE, then averaged).

4. Corrects for the equal-weighting of conditions in the metric despite grossly unbalanced cell counts (e.g. per-group subsampling, group weighting, or per-group error reporting).

5. Fits capacity to the structure of the problem — separate models per marker and/or per condition, or a shared model with explicit condition covariates — with a stated reason why the marker-response mapping should or should not be shared.

6. Reports honestly: per-marker/per-condition performance, variance-reduction steps (ensembling/fold averaging), unused data modalities, and reproducible artefacts or scripts.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: One off-the-shelf regressor is fit on all rows at once with default settings and no held-out evaluation, or evaluation is on the same cells used for training. Masked-marker columns or ID columns may leak into the features. Output is written to the template with no per-marker or per-condition error reporting and no discussion of limitations.

2 — superficial: A single model type is trained with a random train/test split of pooled cells and a global RMSE is reported. Leakage is avoided only incidentally (the target column is dropped) and never discussed. Unbalanced condition sizes, unseen-cell-line generalisation and per-marker differences are not addressed; the summary lists what was run but not what was checked.

3 — competent: Fits a separate model per masked marker (or per marker and condition), excludes target and identifier columns from features on stated leakage grounds, and selects among a couple of regressor families using cross-validated RMSE that matches the scoring metric's error function. Validation is cell-level cross-validation, shuffled to avoid cohort-dominated folds. Summary reports overall and per-marker RMSE but does little about unbalanced group sizes or unseen-cell-line transfer.

4 — thoughtful: Adds an explicit generalisation check to unseen cell lines (leave-one-cell-line-out or similar) and/or unseen conditions, and reports errors aggregated the way the scorer aggregates them — per (cell_line, treatment, time, marker) group, averaged equally. Takes concrete action about the group-size imbalance, such as subsampling or weighting cells per condition, with the metric as the justification. Reduces variance deliberately (multiple model families, fold averaging, or an ensemble) and the write-up names the unused modalities and the residual risks.

5 — expert: The estimator, the loss, the splits and the reporting are all argued from the scoring contract and the biology: training is weighted or resampled so that equally-weighted rare conditions are not drowned out, and validation deliberately withholds cell lines and/or perturbations so that the reported number estimates the actual holdout task. Model capacity is allocated with a reason — per-marker and/or per-condition fits where wiring differs, pooling where data are thin — and instability is controlled by ensembling across genuinely different views or model families, or by a distributional/mechanistic formulation that is justified for what is identifiable per cell. Leakage is reasoned about at the level of what will be observable at prediction time, not just column dropping. The summary gives per-group and per-marker diagnostics, honest failure modes, unused data, and artefacts sufficient to re-run the pipeline.

DREAM/syn20366914/Q2 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn20366914/Q2: task context

TASK CONTEXT (DREAM/syn20366914/Q2):

The data come from a single-cell signalling study of dozens of breast cancer cell lines: each line was profiled by mass cytometry for a panel of phospho-protein markers across several kinase inhibitors (plus an untreated/full condition) and several time points after treatment, alongside bulk molecular layers (RNA, protein, CNV, SNP). The task is to fill in the missing marker values for held-out (cell line, inhibitor, time) conditions listed in a prediction template — i.e. to predict what the single-cell phospho-marker population would look like for a perturbation never measured in that cell line. Scoring is distribution-based, not per-cell: for each condition it compares the predicted vs measured per-marker medians and the full marker-by-marker covariance matrix, sums the two squared-error terms, and averages over conditions (lower is better). Cells cannot be matched one-to-one, so the biologically meaningful unit of prediction is the per-condition population distribution, and the main pitfall is that cell-line identity — not treatment — dominates the variance in these markers, so any model that ignores the target line's own baseline signalling state, or that pools time points and treatments as if interchangeable, will be swamped by inter-line heterogeneity. Secondary pitfalls include very unequal cell counts and irregular sampling times across conditions/batches, marker-specific missingness, and only a few dozen effectively independent cell lines once data are aggregated to condition level.

DREAM/syn20366914/Q2: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn20366914 Q2 task.

Consider:

1. Aligns the estimator with the distribution-based scorer: models the per-condition summary statistics the metric actually compares (marker medians/means and marker-pair covariances) rather than optimising a per-cell loss, and makes the alignment argument explicitly.

2. Produces the required per-cell output in a way that preserves the predicted marginal locations and marker-marker dependence structure (e.g. sampling a synthetic population from the predicted moments, or an equivalent construction), instead of writing constant values that destroy covariance.

3. Gives the second-moment (covariance) structure an explicit predictor or a justified estimate, rather than leaving it implicit, constant, or degenerate.

4. Chooses estimator complexity appropriate to the effective sample size after aggregation (tens of independent cell lines / conditions vs many markers and features), and justifies the choice — shrinkage, sparsity, low-parameter linear models, or variance-reducing ensembling.

5. Validates in a way that matches the test-time generalisation task: holds out whole cell lines and/or whole conditions rather than random cells, and reports the comparison in metric-relevant terms.

6. Benchmarks against a defensible naive baseline (e.g. substituting or averaging an observed condition of the same cell line) and states whether the learned model improves on it; notes limitations such as unused molecular layers or noisy markers.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Fits or fills values with no reference to how the submission is scored: e.g. writes a single constant per marker for every row, or trains a per-cell regressor on shuffled cells and predicts each row independently. The output has near-zero or arbitrary marker-marker covariance and no one notices that half the score depends on covariance. No validation beyond checking the file has the right shape.

2 — superficial: Predicts per-condition marker location (a mean or median copied or regressed from some other condition) and replicates it across all cells of that condition, so the predicted population has essentially no spread or dependence structure. Covariance is never discussed. Validation, if any, is a random cell-level train/test split, which leaks because cells from the same line/condition are highly correlated. No baseline comparison.

3 — competent: States that the scorer compares per-condition medians and covariances and targets both: predicts a location vector and obtains a covariance estimate (even if borrowed from an observed condition of the same line rather than regressed), then emits per-cell rows by sampling a population consistent with those moments. Uses a low-complexity or regularised estimator with a brief justification about few effective samples. Validation holds out something coarser than individual cells, and results are reported, but the split or baseline comparison is not fully argued.

4 — thoughtful: Both moments are explicitly modelled — location and covariance entries each get their own predictor or a clearly reasoned estimate — and the per-cell output is generated so that predicted medians and marker-marker covariances are preserved by construction; this is verified on held-out data. Validation is at the level of whole cell lines and/or whole conditions with an explicit statement of why cell-level splits leak. Estimator complexity is matched to the aggregated sample size with reasoning (shrinkage/sparsity/simple linear over flexible learners), and the learned model is compared against a naive substitution/averaging baseline in metric terms.

5 — expert: Everything at level 4, plus evidence of exploratory analysis driving feature and covariate selection before fitting, and variance-control measures suited to this regime (e.g. ensembling or averaging over feature subsets/proxy conditions rather than relying on a single most-similar condition), each justified by the noisiness of single-cell measurements. Diagnostics interrogate the model's biology as well as its error — e.g. checking that fitted relationships imply most phospho-markers are only mildly perturbed, or that the generated population's medians/covariances reproduce held-out conditions. Limitations are stated concretely (unused RNA/CNV/SNP layers, dropped or unreliable markers, conditions with no informative proxy) with their likely effect on the score. An alternative but equally moment-aligned, leakage-free strategy reaching the same standard of justification scores here.

DREAM/syn20366914/Q3 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn20366914/Q3: task context

> TASK CONTEXT (DREAM/syn20366914/Q3):
> The data come from a single-cell signalling DREAM challenge: several breast-cancer cell lines were treated with kinase inhibitors (plus untreated/EGF-only controls) and profiled by mass cytometry, giving thousands of single cells per (cell line, treatment, time) condition with ~35 phosphoprotein marker intensities, alongside bulk RNA, proteomics, CNV and SNP data for the same lines and a prior-knowledge signalling network. The task is to fill in the marker columns of a prediction template for conditions involving an inhibitor that never appears in the training data, so the prediction is an extrapolation across perturbations rather than an interpolation. Scoring is distribution-based per condition: the squared error of each marker's median plus the squared error of every entry of the marker-marker covariance matrix, averaged over conditions (lower is better). Individual cells cannot be matched one-to-one across conditions, so the real estimand is the joint per-condition distribution, not per-cell values. The main biological pitfalls are that cell-line identity dominates marker levels, that responses shift strongly with time after treatment, that untreated/control conditions are distributionally unlike any inhibited state, and that independent per-marker point predictions destroy the covariance structure that half the score depends on.

DREAM/syn20366914/Q3: biological_appropriateness

> Judge whether the model design and analysis approach are biologically sound for the syn20366914 Q3 task.
> Consider:
> 1. Extent to which the estimand is treated as the per-condition joint distribution of a group of unmatched single cells rather than as per-cell supervised targets.
> 2. Whether the marker-marker covariance structure is explicitly preserved or modelled, instead of being destroyed by independent per-marker point predictions.
> 3. Alignment of the modelling target with the scoring metric (per-condition medians plus covariance entries) and appropriateness of model complexity given the noise, small number of conditions, and p >> n regime.
> 4. Soundness of the extrapolation strategy for a perturbation with zero training examples, and whether the solution recognises that a within-treatment supervised learner cannot generalise to an unseen label.
> 5. Quality of validation: held-out cell lines/treatments or otherwise leakage-free condition-level evaluation, and comparison against a simple baseline to demonstrate added signal.
> 6. Submission integrity: template keys preserved, the required rows per condition populated, and no residual NAs or degenerate columns that would break median/covariance computation.
>
> Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.
> 1 — absent: Fits a per-marker point predictor (or writes a constant) and copies the same value into every cell of a condition, so within-condition variance and all covariance entries collapse to zero. No recognition that cells are unmatched or that covariance is scored. The output may retain NAs, drop or reorder key columns, or have a different row count than the template.
> 2 — superficial: Adds some spread — e.g. independent per-marker noise or per-marker resampling — so variances are non-zero but marker-marker relationships are essentially arbitrary. The model is a generic regressor trained on individual cells with the unseen treatment handled implicitly (or via a one-hot that is never observed), with no argument for why it should transfer. Validation is a random cell-level split that leaks cells from the same condition into train and test; the template is filled correctly but with no NA/row-count check reported.
> 3 — competent: Explicitly treats each (cell line, treatment, time) group as the unit of prediction and produces whole joint observations — e.g. resampling real single-cell rows from a defensible donor pool — so medians and the covariance structure are inherited rather

than fabricated. Uses a simple, low-parameter approach and justifies avoiding a flexible model given single-cell noise. Extrapolation to the unseen inhibitor is a stated surrogate (e.g. aggregate over the other inhibitor conditions) with a reason. Template integrity and absence of NAs are verified.

4 — thoughtful: Decomposes the target into the quantities the scorer uses — per-condition location and pairwise covariance — and estimates each deliberately, then produces template rows that reproduce those statistics. Justifies model simplicity against the small number of conditions and high per-cell noise, or averages/ensembles across models or reference conditions to cut variance. Validation holds out whole conditions or cell lines and is compared against a naive baseline (e.g. substituting a known treatment) to show the added signal is real. Extrapolation to the unseen inhibitor is argued rather than assumed, and controls are excluded from the reference set.

5 — expert: The estimator is derived from the metric: location and full covariance for each unseen condition are predicted as explicit targets, and the submitted rows are constructed so that the scored statistics match those predictions exactly, with a check that the realised medians and covariances of the written file agree with the intended ones. The extrapolation is principled — reference conditions are combined with weights derived from independently justified similarity to the unseen perturbation, and the choice is stress-tested by leaving out whole treatments or cell lines and comparing against both a naive substitution baseline and alternative aggregation schemes. Complexity is chosen and defended for the p >> n, few-conditions regime (regularisation, pooling, or averaging over models/feature subsets), robustness to condition-level outliers and unequal cell counts is addressed, and remaining failure modes for an unmeasured inhibitor are stated honestly. Template keys, row counts and completeness are all validated.

DREAM/syn20366914/Q4 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn20366914/Q4: task context

TASK CONTEXT (DREAM/syn20366914/Q4):

The data come from a DREAM challenge on single-cell signalling in breast cancer: dozens of breast cancer cell lines profiled with mass-cytometry time-course phosphoproteomics under EGF stimulation plus several kinase inhibitors, accompanied by bulk RNA, proteomics, CNV and SNP data for the same lines. The task is to fill in missing phosphoprotein marker values for held-out cell lines at requested (cell_line, treatment, time) rows of a prediction template. Scoring is RMSE computed per (cell_line, perturbation) group over time points and markers and then averaged across groups, so the target is a population-level summary of each condition's single-cell distribution, not individual cells, and every requested row must be present and non-missing. The main biological pitfalls are: single-cell distributions are noisy and heavy-tailed so naive means/individual cells are poor estimators; marker channels differ in dynamic range and some markers are not measured in all lines; the experimental design is unbalanced with drifting/floating-point time labels that must be reconciled with the template grid; and because test cell lines are unseen, the only cell-line-specific information available is that line's own measured conditions (e.g. its untreated/baseline profile), so generalisation must come from borrowing treatment effects across lines while keeping baseline levels line-specific.

DREAM/syn20366914/Q4: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn20366914 Q4 task.

Consider:

1. Frames prediction at the population level for each (cell_line, treatment, time) group, so that whatever is fit to single cells is reduced to a robust group-level estimate before submission.

2. Builds the cell-line-specific input from information actually available for an unseen line (e.g. its own baseline/other measured conditions) rather than from features that require the held-out condition or leak the target.

3. Stratifies the model by biologically meaningful factors — perturbation identity, time after stimulation, and marker — or encodes them so that non-monotone, drug- and time-specific responses are not averaged away.

4. Chooses estimator capacity appropriate to the effective sample size (tens of cell-line groups, p >> n) and justifies the low-variance/regularised or ensembled choice rather than defaulting to a high-capacity learner.

5. Validates by holding out whole cell lines (mirroring deployment on unseen lines) and compares against a naive baseline such as copying the untreated profile, to show a real learnable treatment effect.

6. Delivers a scorable submission: all template key columns preserved, every requested row present, no NA or out-of-range marker values left.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Fits a single global model on pooled rows with treatment and time either dropped or entered as arbitrary numbers, and writes out per-cell predictions or unaggregated values into the template. Validation, if any, is a random row split so cells or conditions from the same cell line appear in both folds. No baseline comparison; some template rows remain NA or the key columns are altered.

2 — superficial: Aggregates to condition level and includes treatment/time as categorical dummies, but trains one pooled model of arbitrary capacity (e.g. a deep or heavily-tuned boosted model) on very few group-level examples with no reflection on sample size. Validation is a random split of groups rather than of cell lines, so the same line informs both train and test. Predictions fill the template completely but no naive baseline is reported.

3 — competent: Predicts group-level aggregates using inputs available for an unseen line (typically that line's own measured/untreated conditions), with the model stratified or explicitly conditioned on treatment, time and marker so drug- and time-specific responses

are preserved. Deliberately selects a low-capacity or regularised estimator on the grounds of few cell lines, and validates with a held-out-cell-line split. Submission is complete, keys intact, no NAs.

4 — thoughtful: Beyond a competent stratified low-capacity model, the solution argues the transfer logic explicitly — baseline levels are cell-line specific while the treated-versus-untreated mapping is borrowed across lines — and constructs features accordingly (e.g. summaries of the same line's other conditions at matching times). It benchmarks against the naive copy-the-untreated baseline and reports the improvement per group, and it excludes training pairs with incomplete marker vectors instead of imputing them into the fit. Leave-cell-line-out validation is used to choose among several candidate strategies, not just to report one number.

5 — expert: The modelling design is derived from the challenge's biology and metric end-to-end: the estimation target is the group distribution summary, the covariates are restricted to what an unseen line can supply, stratification by perturbation/time/marker is justified by the kinetics being non-monotone and drug-specific, and capacity is bounded (shrinkage, univariate fits, or a variance-reducing ensemble) with the small number of independent cell lines named as the reason. Multiple strategies are compared under leave-cell-line-out validation against the naive untreated-copy baseline, and the winning model's coefficients or residuals are interpreted biologically to confirm the gain comes from real inhibitor effects rather than identity mapping. The submission is verified row-by-row against the template and remaining limitations (unused modalities, thin conditions) are stated. An equally sound alternative design that satisfies the same reasoning also earns this level.

DREAM/syn4231880/Q1a The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn4231880/Q1a: task context

TASK CONTEXT (DREAM/syn4231880/Q1a):

The data are ~2,200 measured Loewe synergy scores for ~170 unordered drug-pair combinations tested across a panel of cancer cell lines, together with per-drug monotherapy dose-response parameters (potency, maximum effect, curve slope, maximum tested concentration), and baseline Sanger molecular profiles of the cell lines (gene expression, somatic mutations, copy number, tissue/lineage metadata). The task is to predict the synergy score for held-out cell-line/combination pairs. Scoring is a weighted average of the Pearson correlation computed *within* each drug combination, weighted by sqrt(n_cell_lines-1), so only the ranking of cell lines within a combination matters — global offsets or per-combination scale differences are nuisance variance, and any combination given a constant prediction scores zero. The dominant pitfall is extreme data scarcity relative to feature dimensionality: roughly ten labelled cell lines per combination against tens of thousands of omics variables, so genome-wide features overfit unless restricted by mechanistic prior knowledge, and baseline omics features alone are constant across all combinations in a cell line and therefore cannot discriminate between combinations at all. Secondary pitfalls are the arbitrary ordering of compound A vs B within a symmetric combination label, noisy/outlier synergy values, and the temptation to build features from a row's own label. A tight compute budget means choices must be made deliberately rather than by brute force.

DREAM/syn4231880/Q1a: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn4231880 Q1a task.

Consider:

1. Alignment of the fitting objective and label preprocessing with the within-combination correlation metric (e.g. removing between-combination location/scale as nuisance, or otherwise arguing why raw-scale fitting is adequate), and avoidance of constant predictions for any combination.

2. Appropriateness of the estimator family to the data geometry: nonlinear/interaction-capable or structure-exploiting learners justified against the non-additive nature of synergy, versus regularised low-variance alternatives justified against p >> n; the choice is argued rather than defaulted.

3. Honesty of the validation design given the per-combination metric and the sparse cell-line x drug-pair design — e.g. splits grouped or stratified by combination and/or cell line, mirroring what is unseen at test time, and reporting where performance depends on train/test overlap.

4. Whether engineered feature families and data modalities are added or dropped on held-out evidence, including documented rejections, rather than retained on assumption.

5. Whether label-derived or aggregate features are constructed without using the row's own outcome, and whether outliers/low-quality synergy measurements are handled with a stated rule instead of silently included or silently deleted.

6. Whether model selection and combination, if any, are performed on out-of-fold rather than in-sample estimates, and whether the choice of a single model versus a combination of models is justified with respect to variance and the small sample size.

7. Whether the write-up scopes the irreducible noise in synergy measurements and the generalisation limits of the validation design, instead of presenting validation numbers as clinical performance.

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: A single model is fitted on the default target with default settings, evaluated (if at all) on a plain random row split, and applied to the test set. Nothing is checked about whether every combination receives varying predictions, nothing is validated by combination or cell line, and no feature family is ever tested and discarded. Outliers, duplicate rows and quality flags are not mentioned; validation error is reported as if it were the expected test performance.

2 — superficial: Cross-validation is run but only as random k-fold over rows, so combination- and cell-line-level structure leaks across folds and the estimate is optimistic. Hyperparameters may be tuned, but the objective is left untouched relative to the within-combination metric, and feature blocks are kept or dropped by intuition rather than held-out comparison. Any aggregate or target-derived feature is computed over all rows including the row being predicted, or the possibility of such leakage is not addressed.

3 — competent: The estimator choice is justified with respect to sample size and to synergy being a non-additive interaction, and hyperparameters are tuned by cross-validation rather than fixed. At least one split scheme reflects the evaluation structure (grouped or stratified by combination, or by cell line), and the metric's per-combination nature is acknowledged in how results are read. Obvious leakage in label-derived features is avoided, and one or two feature families are compared on held-out data before being kept.

4 — thoughtful: Multiple validation schemes are compared (random versus grouped by combination and/or cell line) and the gap between them is interpreted as evidence about what the model actually generalises over. Labels or the objective are handled so as to target within-combination ranking rather than absolute magnitude, with the reasoning stated, and a rule for outlier or low-quality synergy rows is given and applied. Feature families and modalities are ablated on held-out data with rejections documented; model selection or combination, if used, is based on out-of-fold rather than in-sample estimates and the single-versus-combined choice is justified by variance at this sample size.

5 — expert: Every design decision is traced to the scoring geometry and the sparse experimental design: the objective/label treatment, the split structure, and the estimator are each argued against the fact that only ~10 cell lines support each combination and only within-combination ranking is rewarded, and constant-prediction failure modes are explicitly guarded against. Marginal contributions of components are attributed by systematic held-out experiments, with negative results and redundant modalities reported rather than hidden, and any ensembling/weighting is derived from out-of-fold predictions with a stated variance rationale. The write-up bounds its own claims: it states the intrinsic noise ceiling of Loewe synergy measurements, notes how much performance rests on train/test overlap in cell lines or drugs, and flags which apparent biomarkers are artefacts of the model's own assumptions.

DREAM/syn4231880/Q1b The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn4231880/Q1b: task context

TASK CONTEXT (DREAM/syn4231880/Q1b):

The data comes from the AstraZeneca-Sanger Drug Combination Prediction DREAM challenge: a sparse table of (cell line, drug-A + drug-B combination) experiments with a measured synergy score, plus cell-line molecular profiles restricted in this subchallenge to copy-number (SNP6.0) and whole-exome mutation calls, and whatever external prior knowledge the solver brings (drug targets, pathways, PPI/signalling networks, chemical properties, annotation of the assay design). Mono-therapy dose-response readouts and any other molecular/clinical readouts are explicitly forbidden as inputs. The task is to predict synergy for held-out cell-line/combination pairs and write CELL_LINE, COMBINATION_ID, PREDICTION for every row of the held-out list. Scoring is a weighted Pearson correlation computed *within* each drug combination and then averaged with weights sqrt(n_cell_lines - 1), so only the ranking of cell lines within a combination matters — a model that nails between-combination differences but is flat within a combination scores near zero, and constant predictions for a combination score exactly zero. The biology imposes two main pitfalls: each combination has only a handful of cell lines while CNV/mutation feature spaces are tens of thousands of columns wide (severe p >> n overfitting), and unperturbed cell-line features alone are identical for every combination in a cell line, so some drug-aware or combination-aware representation is required for the model to vary within a cell line at all. Drug order in a combination is arbitrary, cell-line identifiers differ between resources, and synergy scores are noisy replicate-limited measurements with quality flags.

DREAM/syn4231880/Q1b: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn4231880 Q1b task.

Consider:

1. Whether the modelling target and features are aligned to the within-combination scoring structure (predictions must vary across cell lines within a combination; between-combination offsets are irrelevant or actively removed).

2. Whether the problem is framed with awareness of the sparse cell-line x drug x drug structure — sharing strength across combinations and/or cell lines instead of fitting each combination in isolation or pooling blindly.

3. Rigour of the validation design: cross-validation schemes that reflect the scoring unit (grouped/stratified by combination or cell line), reported alongside the acknowledged optimism of random splits.

4. Whether high-dimensional genomic or descriptor feature blocks are added on empirical evidence and dropped by honest ablation when they overfit, rather than accumulated because 'more omics is better'.

5. Handling of label noise and quality: use of QA/replicate flags, outlier or range screening, and shrinkage/ensembling choices that stabilise a noisy continuous outcome.

6. Whether leakage and generalisation limits are diagnosed and stated (aggregate/target-derived features constructed leave-one-out, dependence on train/test overlap of cell lines or drugs, no use of held-out gold).

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: Fits one model on a pooled feature-label table with a single random train/test split (or no held-out evaluation at all) and never checks that predictions vary within a combination; some combinations may receive near-constant or constant predictions, which the metric scores as zero. No ablation, no noise handling, no leakage discussion. Output file is produced and covers the required rows, but nothing in the workflow reflects the per-combination scoring or the sparse tensor structure.

2 — superficial: Runs a plain regression with default hyperparameters and a random k-fold split, reporting a global correlation rather than anything resembling the per-combination weighted metric. Genomic features are thrown in wholesale with no ablation; noisy labels and QA flags are ignored. Predictions do vary within combinations, but only incidentally,

and there is no check of whether the variation comes from cell-line signal or from combination-level offsets. Leakage risks (e.g. target-derived aggregates, repeated cell lines) are unexamined.

3 — competent: Evaluates with cross-validation that is at least stratified or grouped in a way relevant to the scoring unit, tunes key hyperparameters rather than using defaults, and computes an internal approximation of the per-combination weighted correlation to guide choices. Runs at least one honest ablation and drops a feature block that fails to help. Notices that combination-level mean offsets do not contribute to the metric and takes some step about it (e.g. centring per combination or including combination identity). Ensembling or regularisation is used sensibly for a small noisy dataset, and obvious leakage (using the target row in its own aggregate feature) is avoided.

4 — thoughtful: Design decisions are visibly driven by the metric and the data geometry: the target and/or features are transformed so the model is optimising within-combination ranking, and strength is deliberately shared across combinations and cell lines (similarity-based grouping, marginal row/column baselines built leave-one-out, or a factorisation view of the sparse tensor). Multiple holdout schemes are compared and the optimism of the loosest one is stated. Feature dimensionality is capped with an argument tied to the number of labelled synergy points, several feature blocks are tested and pruned on out-of-fold evidence, and label quality flags or outliers are screened. Ensemble weights are set on out-of-fold predictions rather than on the selection data.

5 — expert: The whole pipeline is reasoned end-to-end from the metric and the sparsity pattern: the representation guarantees predictions differ across cell lines within every combination, between-combination variance is handled explicitly, and the training signal for each prediction is drawn from the observations that actually inform it (co-located cell lines / shared drugs / mechanistically similar combinations), with symmetry-respecting augmentation where used. Model and feature-count selection rest on many systematic cross-validated comparisons under several holdout schemes, with feature blocks and even whole modalities added or dropped on evidence. Label noise is addressed (quality filtering, trimming, ensembling of heterogeneous learners), feature importances are interpreted with stated caveats, and the report names the concrete generalisation limits — which train/test overlaps the score depends on, what would break outside this design — with no use of held-out gold and a reproducible record of every derived input.

DREAM/syn4231880/Q2 The extension prepends this task context; the original cohort receives only the criterion below.

DREAM/syn4231880/Q2: task context

TASK CONTEXT (DREAM/syn4231880/Q2):

The data comes from a pharmacology screen in which pairs of compounds were tested across cancer cell lines: for each drug pair and cell line there is a measured synergy score, plus monotherapy dose-response curves for each drug in each cell line, and molecular characterisation of the cell lines (gene expression, mutations, copy number, methylation) and compound annotation (nominal targets, chemistry). The task is to output a binary matrix over the held-out (COMBINATION_ID x CELL_LINE) pairs, marking 1 where the pair is predicted to be synergistic, for combinations that have little or no direct synergy training data. Scoring is the signed -log10 p-value of the prediction term in a global three-way ANOVA on observed synergy with drug-combination label and cell-line label as covariates, so only the variance the binary call explains *after* combination and cell-line main effects are removed counts; an all-0 or all-1 matrix scores zero, and a call that merely recovers which combinations or which cell lines are generally synergistic earns nothing. The biology imposes two main pitfalls: there are far more molecular features than labelled synergy measurements (so unrestricted genome-wide features overfit), and any feature that depends only on the cell line gives identical predictions for every combination in that cell line (and vice versa), which is exactly the variance the metric has already absorbed. Useful solutions therefore have to build features that vary jointly with drug pair and cell line (e.g. monotherapy sensitivity, target/pathway context), transfer information across mechanistically similar combinations, and choose the positive-call rate/threshold deliberately rather than by default.

DREAM/syn4231880/Q2: biological_appropriateness

Judge whether the model design and analysis approach are biologically sound for the syn4231880 Q2 task.

Consider:

1. Whether the solution recognises that the scored statistic conditions on combination and cell-line main effects, and shapes the target, features or thresholding so predictions carry information orthogonal to those covariates.

2. Whether the prediction varies jointly across combinations and cell lines (rather than reducing to a per-combination or per-cell-line call) and whether that degeneracy is checked in the output matrix.

3. Appropriateness of the validation design to the stated regime of predicting combinations without direct training data (e.g. combination-grouped or otherwise leakage-aware splits) versus random-row cross-validation.

4. How the continuous-to-binary decision and the positive-call rate are chosen: deliberately, against the scored objective or class imbalance, versus an arbitrary default that risks a near-degenerate matrix.

5. Choice of estimator and variance control suited to a small, noisy, high-dimensional problem (interaction-capable or regularised learners, ensembling/averaging, hyperparameters chosen by validation rather than assumed).

6. Whether noisy or degenerate training records are filtered on principled grounds (assay quality, outliers, excluded combinations) and whether the solution honestly states the limits of its generalisation (e.g. reliance on overlap of cell lines or single drugs between train and test).

Assign ONE integer score from 1 to 5. Each level is defined by a concrete example for this task; pick the level whose example best matches what the solution actually did. Do not average the sub-checks — score the level the work as a whole reaches.

1 — absent: A single off-the-shelf model is fit on whatever matrix was assembled and thresholded at an arbitrary default, with no validation beyond a single random train/test split (or none at all). The output matrix is never inspected, so it may be nearly all zeros, nearly all ones, or constant down every row or column. The three-way-ANOVA metric is never discussed, and there is no filtering of noisy synergy records or statement of limitations.

2 — superficial: Cross-validation is run, but only on random rows, so combination identity leaks across folds and the reported performance does not reflect predicting unseen combinations. Binarisation uses a fixed cutoff or top-k rate chosen without reference to the

metric or to class imbalance, though the solution does at least check that both classes appear in the output. The metric is quoted but treated as ordinary classification accuracy; the fact that combination and cell-line effects are already removed is not used anywhere in the design.

3 — competent: The task is framed to match the scored binary outcome, model family and hyperparameters are chosen by comparing candidates under cross-validation, and class imbalance is addressed (weighting, resampling or an explicitly tuned call rate) so the matrix is not near-degenerate. At least one validation scheme approximates the unseen-combination regime, and the covariate-adjusted nature of the ANOVA is acknowledged in words. Obvious quality filtering of training synergy records is applied, and basic limitations are stated.

4 — thoughtful: The scoring logic is read carefully and acted on: the solution removes or conditions out per-combination and/or per-cell-line variance in the target or the decision rule so that the binary call explains residual variance, and verifies the output varies within both rows and columns. Multiple holdout schemes (random, stratified, grouped by combination) are compared and the pessimistic one is used for decisions; the threshold or positive rate is selected against a validation surrogate of the scored objective rather than accuracy. Variance is controlled by ensembling or regularisation with out-of-fold-based weighting, training records are filtered on quality/outlier grounds, and the write-up names the remaining generalisation risk.

5 — expert: The solution derives its whole prediction strategy from the sequential variance decomposition of the metric — showing which prediction patterns can be significant at all — and constructs features conditioned jointly on drug pair and cell line so the call is not a restatement of a main effect; encodings are made invariant to arbitrary drug ordering within a pair. Model selection, thresholding and ensembling are all evaluated under leakage-aware splits with quantified ablations that report which components help and which hurt, including cases where a biologically appealing modality was dropped on evidence. It explicitly trades balanced accuracy against the primary objective when they conflict, justifies the trade, and closes with an honest diagnosis of the regime it actually generalises in (e.g. dependence on overlapping cell lines or single agents) plus how its own assumptions bias apparent feature importance. An equally rigorous alternative route (tensor completion, similarity-based transfer, or nonlinear ensemble) reaches this level if the same reasoning is displayed.
