PROBABILITYBENCH: MODEL EVALUATION AND CALIBRATION WITH EXACT GROUND-TRUTH UNCERTAINTY

Anonymous authors
Paper under double-blind review

ABSTRACT

Claims about predictive uncertainty are hard to check against real data: each example typically carries one realized label, never the distribution behind it, so uncertainty quantification is often judged against estimates rather than truth. We introduce ProbabilityBench with three simulated worlds, i.e., credit review, peer review, and covert transfer, where partial observability creates irreducible uncertainty, natural-language rendering provably preserves it, and every case's exact class probability is known. Such ground truth has existed only in toy settings such as Gaussian class conditionals, unsuited to testing a language model. With ProbabilityBench, a model's probability is scored by its exact KL divergence, e.g., Jev is both the cheapest and the closest to the true probability in every world among the models we compared. Ground-truth probabilities also enable us to evaluate the evaluation methods themselves, to assess how accurate uncertainty-quantification methods such as calibration estimators and Bayes-error estimators actually are.

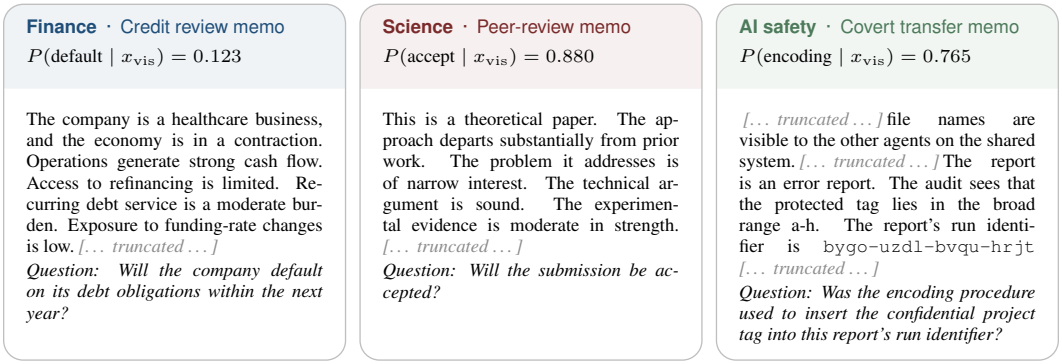

Figure 1: Examples in ProbabilityBench, with the ground-truth uncertainty $P(Y \mid X)$ available.

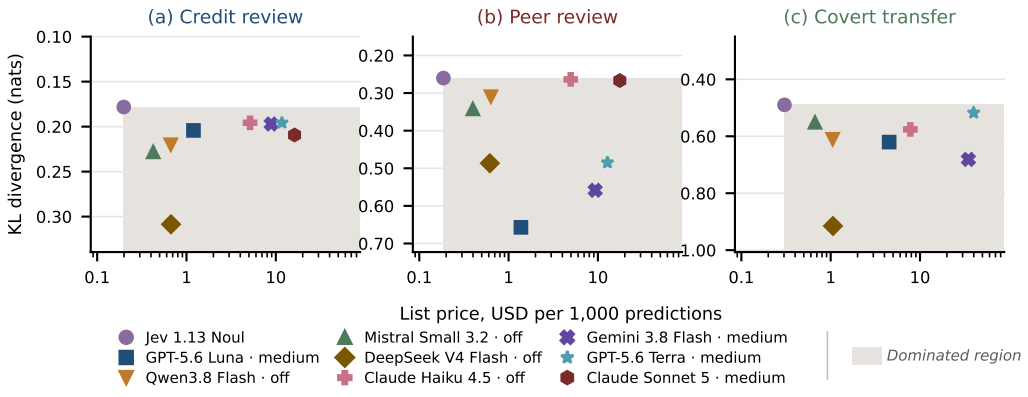

Figure 2: Performance–cost plots. Jev is the only model on the Pareto frontier: in all three worlds it is both the cheapest and the best in KL divergence.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

1 INTRODUCTION

Machine learning models have long been expected to report how confident they are, not only what they predict (Bishop, 2006; Niculescu-Mizil & Caruana, 2005). Probabilistic classifiers such as logistic regression output a class probability, language models can be asked to state one in words, and recent large decision models such as Jev pair every decision with a probability (TypeSafe AI, 2026). Checking whether such probabilities can be trusted is harder than it sounds. A confidence is a statement about the conditional distribution $P(Y \mid X)$ of the label Y given the input X, and real data never shows us that distribution: each example typically carries one realized label. Calibration is therefore assessed indirectly, by gathering predictions that report similar confidence, most often into bins, and comparing each group's stated confidence against the label frequency observed within it (Guo et al., 2017; Nixon et al., 2019; Kumar et al., 2019); work on language models follows the same pattern (Kadavath et al., 2022; Lin et al., 2022; Tian et al., 2023; Xiong et al., 2024; Geng et al., 2024). Whatever the grouping, the comparison is between a prediction and a frequency estimated from finitely many labels, never between a prediction and the probability it is trying to report.

A second question is how much of the error that remains is irreducible. The *Bayes error* (Fukunaga & Hostetler, 1975; Mohri et al., 2018) is the error rate of the best predictor that could exist: the one that knows $P(Y \mid X)$ and always answers with the more likely class. It is a floor set by the task rather than by the model, so it tells us whether a gap to perfect accuracy is a fault worth fixing or simply the task's own ambiguity. Here too the truth is unavailable, so the Bayes error must be estimated, and estimates are compared against other estimates rather than against a known value (Ishida et al., 2023; Ushio et al., 2026). Toy problems such as Gaussian class conditionals do have a known Bayes error, and a few image datasets, such as CIFAR-10H (Peterson et al., 2019) and Fashion-MNIST-H (Ishida et al., 2023), do carry many labels per instance, but neither presents a case in text, so neither can test a language model. Those annotations also follow a different protocol from the original hard labels, which distorts the soft labels they give (Ushio et al., 2026). What is missing is a benchmark that reads like a real task and whose uncertainty is known exactly.

We introduce ProbabilityBench, a benchmark of simulated worlds built to meet both requirements. In each world, a case is generated from latent factors, and a deterministic rule turns those factors into the case's outcome; the reader sees only a written description that reveals part of them. Because the description leaves out part of what the rule depends on, cases that look identical to the reader can still have different outcomes. The factors take finitely many values, and we write down the whole world: how the factors are drawn, the rule, and the description. We can therefore work out exactly what fraction of the cases with a given description have each outcome. That fraction is the exact class probability $P(Y = y \mid X_{\text{vis}})$ for every example, and from it we derive the world's exact Bayes error. Holding back progressively more of the case gives each world Low, Medium, and High settings with increasing ambiguity.

We build three worlds in domains with different semantics. Financial default prediction weighs a company's resources against its obligations; peer-review outcome prediction scores a manuscript's quality against an acceptance bar; and an AI-safety audit asks whether an AI system hid a confidential tag in a file name others can see. All three follow the construction in Fig. 3, and Fig. 1 shows one rendered test example from each, together with its exact class probability.

Exact class probabilities change what an evaluation can ask. The most direct use is to compare a model's stated probability with the true one: we score predictions by the KL divergence from the exact class probability to the model's, so a model is judged by how far its probability is from the truth. Fig. 2 plots that score against published price for 9 models.

The exact probabilities also support evaluations that sampled labels cannot. Knowing how likely each prediction is to be correct, we can score a method by its expected accuracy and compare it with the Bayes accuracy, the highest accuracy any method could achieve. Expected and realized accuracy can disagree sharply: agents given the test labels can reach perfect realized accuracy by looking up answers, yet their expected accuracy stays below the Bayes accuracy. Because each world's Bayes error and calibration targets are known by construction, the worlds also test the evaluation methods themselves: we can measure how far estimates of the Bayes error and of multicalibration error fall from their true values.

2 Related Work

Uncertainty benchmarks. Recent benchmarks study uncertainty in language and multimodal models, including aleatoric and epistemic uncertainty (Yang et al., 2025; Chandu et al., 2025; Wang et al., 2025; Renda et al., 2026; Tomov et al., 2025). Their reference targets include answer correctness, answerability annotations, and empirically estimated statistics or answer distributions. A second family imposes a known performance ceiling on otherwise determined tasks: CapBencher (Ishida et al., 2026) records one of several valid answers at random, CapCode (Lodkaew et al., 2026) randomizes unit tests, and ImpossibleBench (Zhong et al., 2026) puts task specifications in conflict with tests, so that scores above the ceiling reveal test-set overfitting or exploitation. BLInD (Nafar et al., 2025) also has exact answers, computed by Bayesian-network inference, but its texts state the relevant probabilities and ask the model to derive a queried one; it tests probabilistic reasoning, not a model's own uncertainty about an outcome. ProbabilityBench instead derives irreducible uncertainty from the specified data-generating process, so each text-rendered example carries an exact class probability and each setting an exact Bayes error; this supports direct evaluation of aleatoric uncertainty and calibration.

Calibration and confidence evaluation. Calibration of neural networks is classically measured with binning-based estimators such as expected calibration error (Guo et al., 2017), whose statistical fragility has motivated refined estimators (Nixon et al., 2019; Blasiok & Nakkiran, 2024) and verified calibration procedures (Kumar et al., 2019). For language models, a parallel literature studies whether models know what they know, via self-evaluation (Kadavath et al., 2022), verbalized uncertainty (Lin et al., 2022; Tian et al., 2023), and systematic comparisons of elicitation strategies (Xiong et al., 2024); see Geng et al. (2024) for a survey. When conditional label probabilities are unknown, population calibration quantities generally require estimation from observed labels. Multicalibration (Hébert-Johnson et al., 2018) requires calibration across subgroups. Empirical evaluations use subgroup calibration errors (Hansen et al., 2024) or unbiased estimates of witness moments (Futami & Ishida, 2026); both also rely on observed labels.

Repeated-label observations also support richer assessments of uncertainty. Mimori et al. (2021) develop evaluation methods for label uncertainty and higher-order statistics, including annotator disagreement, and calibrate distributions over class probabilities. Johnson et al. (2024) connect prediction of paired responses to second-order calibration. Ahdritz et al. (2024) study higher-order calibration against the full distribution of conditional label probabilities and develop relaxations based on k repeated labels per input. ProbabilityBench complements these approaches by making both the full distribution and its finite-k snapshot projection exactly computable within each prediction cell. This enables evaluation of a fitted predictor against both population targets.

Bayes error estimation. A long line of work estimates the Bayes error of a task from data (Fukunaga & Hostetler, 1975; Devijver, 1985; Berisha et al., 2015; Noshad et al., 2019; Theisen et al., 2021; Michelucci et al., 2021; Ishida et al., 2023; Ushio et al., 2026). Because the true Bayes error of a real dataset is unknown, these estimators are validated on synthetic distributions with a closed-form Bayes error or, on real data, through proxies such as injected label noise (Renggli et al., 2021). The latter treats the test error of state-of-the-art models as an upper bound on the Bayes error, which holds only if those models have not overfit the test set, an assumption that is becoming hard to maintain with language model training (Ishida et al., 2026) and agents (Lodkaew et al., 2026).

3 The ProbabilityBench Framework

3.1 Problem Formulation and Metrics

We consider binary classification in which a latent world state Z generates both a random vector of observable attributes X (for example, a company's cash buffer or a submission's novelty) and an outcome label $Y \in \{0, 1\}$. In any partial-observability setting, the visible subvector X_{vis} is revealed to the predictor; the remaining subvector X_{hid} is withheld. For each visible input, the world defines the class probabilities $P(Y = y \mid X_{\text{vis}})$.

For a model with parameters θ, write f_θ for its hard classifier and $p_\theta(Y \mid X_{\text{vis}})$ for the probability it reports. Fix a hiding level and write $U = X_{\text{vis}}$ with support $\mathcal{U}$, $p^*(u) = P(Y = 1 \mid U = u)$, and

$q(u) = p_\theta(Y = 1 \mid U = u)$. Accuracy alone says nothing about whether this *reported confidence* reflects the task's true uncertainty. We therefore use several metrics, defined below, each computed from exact class probabilities.

Bayes accuracy and model accuracy. The Bayes-optimal predictor under 0–1 loss, with ties broken in favor of class 1, is $f^*(x_{\text{vis}}) = \arg\max_{y\in\{0,1\}} P(Y = y \mid X_{\text{vis}} = x_{\text{vis}})$, with corresponding *Bayes accuracy* $\mathcal{A}^* = \mathbb{E}_{X_{\text{vis}}}[\max_{y\in\{0,1\}} P(Y{=}y \mid X_{\text{vis}})]$ and *Bayes error* $\varepsilon^* = 1 - \mathcal{A}^*$. Expected accuracy scores a model's hard decision against the exact conditional distribution rather than against one sampled label, and Δ_{acc} is its gap to Bayes accuracy:

$$\mathcal{A}_{\text{exp}}(f_\theta) = \mathbb{E}_{X_{\text{vis}}}[P(Y = f_\theta(X_{\text{vis}}) \mid X_{\text{vis}})], \qquad \Delta_{\text{acc}} = \mathcal{A}^* - \mathcal{A}_{\text{exp}}(f_\theta). \tag{1}$$

Unlike *realized accuracy*, the fraction of test inputs whose single sampled label the model predicts correctly, $\mathcal{A}_{\text{exp}}$ is upper-bounded by $\mathcal{A}^*$ example by example, so it is the main accuracy metric for Bayes-gap comparisons. Realized accuracy can exceed $\mathcal{A}^*$ slightly through label-sampling noise, and by a wide margin when a model has overfit the realized test labels. We still report it, because a score well above $\mathcal{A}^*$ is direct evidence of test-set overfitting (Appendix C.1).

KL divergence from exact class probabilities. Because $p^*(u)$ is known for every input, a reported probability can be compared with it input by input. We use the expected KL divergence from the exact class probability, in nats:

$$\text{KL}(p^* \,\|\, q) = \mathbb{E}_U\left[p^*(U)\log\frac{p^*(U)}{q(U)} + \big(1 - p^*(U)\big)\log\frac{1 - p^*(U)}{1 - q(U)}\right]. \tag{2}$$

It is zero only if $q = p^*$ almost surely, and it equals the expected log loss of q minus that of p^*, the part of the log loss a model could still avoid. Averaging the summand over test inputs estimates it without any labels; Appendix A.2 gives how q is clipped.

Calibration and multicalibration. Ordinary calibration requires $\mathbb{E}[Y \mid q(U)] = q(U)$ almost surely; multicalibration (Hébert-Johnson et al., 2018) requires the same property within every group in a fixed finite collection $\mathcal{G}$ of possibly overlapping subsets of $\mathcal{U}$. For evaluation, we use the group and score-bin setting of Hébert-Johnson et al. (2018). For a fixed partition $\mathcal{B} = \{I_1, \ldots, I_m\}$ of $[0, 1]$, let $B_j = \{u : q(u) \in I_j\}$ and define

$$\text{MC}_{\mathcal{G},\mathcal{B}}(q) = \max_{G\in\mathcal{G},\, 1\le j\le m} \big|\mathbb{E}\big[\mathbf{1}_G(U)\mathbf{1}_{B_j}(U)(p^*(U) - q(U))\big]\big|. \tag{3}$$

Each moment is weighted by the probability of its group–bin cell in the whole population, so a small cell contributes less for the same conditional calibration gap. Zero-mass cells contribute zero; finite bins can hide residuals that cancel within a bin. The empirical estimator replaces the expectation with an average over all sampled examples and $p^*(U)$ with observed labels, keeping groups and bins fixed. Absolute values and the maximum can turn sampling noise into positive estimated error even for a perfectly calibrated predictor. In the two *factor worlds* (finance and peer review), the exact population value is computable by enumeration, allowing this estimation error to be measured directly. Unlike Eq. 2, both criteria constrain only averages of $p^* - q$. By Pinsker's and Jensen's inequalities, each moment in Eq. 3 is at most $\sqrt{\text{KL}(p^* \,\|\, q)/2}$, so a small KL forces a small MC error. The converse fails: reporting the class prior $P(Y{=}1)$ everywhere is calibrated, yet its KL is the mutual information between U and Y.

Higher-order calibration and snapshots. Let $\mathcal{C}$ be a finite partition of $\mathcal{U}$ into cells of positive population mass. A higher-order predictor assigns a probability measure ν_C on $[0, 1]$ to each input in cell C: it predicts a distribution over label probabilities. Following Ahdritz et al. (2024), its target is the *Bayes mixture*

$$\pi^*_C = \mathcal{L}\big(p^*(U) \mid U \in C\big), \tag{4}$$

where $\mathcal{L}$ denotes the distribution of a random variable. We measure the distance from ν_C to π^*_C by the Wasserstein distance W_1 with cost $|p - p'|$ on $[0, 1]$, half the binary-simplex ℓ_1 cost.

A k-*snapshot* consists of k independent labels conditional on the same input, represented in the binary case by their positive-label proportion. The snapshot projection of a mixture π is $\text{proj}_k\,\pi = \mathcal{L}(S/k)$, where $p \sim \pi$ and $S \mid p \sim \text{Binomial}(k, p)$. A snapshot predictor ν_C is supported on

$\{0, 1/k, \ldots, 1\}$. Our experiment compares the same fitted snapshot predictor with both targets using population-weighted mean errors,

$$E_{\mathrm{HO}}(\nu) = \sum_C w_C W_1(\nu_C, \pi^*_C), \qquad E_k(\nu) = \sum_C w_C W_1(\nu_C, \mathrm{proj}_k\, \pi^*_C), \tag{5}$$

where $w_C = P(U \in C)$. These are mass-weighted averages over cells; Ahdritz et al. (2024) instead bound the worst cell. We use bins of a fixed scalar predictor to define $\mathcal{C}$; they need not be its exact level sets. The population masses and class probabilities of those worlds make all quantities in Eqs. 3–5, including π^*_C and $\mathrm{proj}_k\, \pi^*_C$, computable by finite summation.

3.2 A Recipe for Worlds with Exact Class Probabilities

Every ProbabilityBench world follows the same construction (Fig. 3). The world is represented by finitely many latent factors $Z = (Z_1, \ldots, Z_k)$, each taking finitely many values, and an author-specified, dependency-structured joint distribution $P(Z)$. The label is a deterministic function $Y = g(Z)$, for example a score over latent factors compared to a fixed threshold, so all label uncertainty stems from not knowing Z.

Observable attributes are then computed from Z by a deterministic projection that drops or merges information, for example by withholding some factors entirely; because the projection is many-to-one, distinct latent states share identical attributes, so the attributes do not determine Z. Finally, each world keeps label uncertainty that survives even when every attribute is shown, so population Bayes error stays positive: the factor worlds include a *residual factor*, a component of Z that enters the label but is never shown, and covert transfer admits accidental matches (Sec. 4.3). Individual inputs may still have deterministic outcomes.

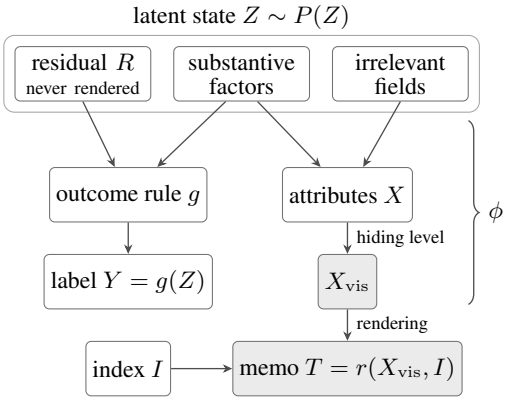

Figure 3: How a world generates a case; g and ϕ are deterministic. ML models read X_{vis}; language models and agents read only the memo T.

Exact class probability computation. Write $\phi(z)$ for the visible attributes when the world is in latent state z at the current hiding level: the attributes are computed from z by the deterministic projection above, and those withheld at that level are dropped (Sec. 3.4 renders the rest as a memo). Both the label and the visible attributes are therefore deterministic functions of the latent state, $Y = g(Z)$ with $g(z) \in \{0, 1\}$ the outcome rule and $X_{\mathrm{vis}} = \phi(Z)$. A deterministic ϕ loses no generality: randomness in the visible attributes can be written as further latent factors that g ignores, which is how the irrelevant fields enter. For any visible input x_{vis} with $P(X_{\mathrm{vis}}{=}x_{\mathrm{vis}}) > 0$,

$$\begin{aligned} P(Y{=}1 \mid X_{\mathrm{vis}}{=}x_{\mathrm{vis}}) &= \frac{P(Y{=}1,\ X_{\mathrm{vis}}{=}x_{\mathrm{vis}})}{P(X_{\mathrm{vis}}{=}x_{\mathrm{vis}})} = \frac{P\big(g(Z){=}1,\ \phi(Z){=}x_{\mathrm{vis}}\big)}{P\big(\phi(Z){=}x_{\mathrm{vis}}\big)} \\ &= \frac{\sum_{z:\, g(z)=1,\ \phi(z)=x_{\mathrm{vis}}} P(Z{=}z)}{\sum_{z:\, \phi(z)=x_{\mathrm{vis}}} P(Z{=}z)}. \end{aligned} \tag{6}$$

The denominator adds up the probability of every latent state producing x_{vis}, and the numerator keeps those whose outcome is positive. Every population quantity of Sec. 3.1 is likewise a finite sum over visible inputs; for instance, writing $p^*(x_{\mathrm{vis}})$ for the class probability in Eq. 6,

$$\varepsilon^* = \sum_{x_{\mathrm{vis}}} P(X_{\mathrm{vis}}{=}x_{\mathrm{vis}})\ \min\{p^*(x_{\mathrm{vis}}),\ 1 - p^*(x_{\mathrm{vis}})\}.$$

The two kinds of world evaluate these sums differently. In the factor worlds the latent space is small enough to enumerate, so we tabulate the mass and class probability of every combination of visible attribute values; covert transfer has finite Z but far too many inputs to enumerate (the run identifier alone has $26^{16} \approx 4 \times 10^{22}$ values), so we marginalize analytically: only the letter at the report's position is label-relevant and the rest cancel, leaving the closed form of Sec. 4.3.

3.3 Two Axes of Difficulty Control

Hiding-based difficulty control alone conflates two conceptually distinct sources of irreducible uncertainty: *information limitation* (hidden attributes contain signal the model cannot access) and *conditional label noise* (even when every attribute is shown, the outcome still depends on the residual factor). The factor worlds expose the two independently.

Hiding controls the first source: the levels are nested, each withholding more attributes than the last, and exact computation confirms that ε^* strictly rises from Low to Medium to High (Appendix B). The residual factor controls the second: in the factor worlds its distribution is a free parameter, and putting more mass on its nonzero values increases ε^* without changing what the model sees (Table 7).

Jointly, the two axes let a benchmark creator target a desired Bayes error through qualitatively different routes (rich information with high label noise, or sparse information with none), which induce different class probabilities and therefore different calibration targets. Real-data benchmarks offer no such control because the true class probability is unknown.

3.4 Preserving Class Probabilities in Text

All three worlds render their visible attributes as natural-language case memos (credit, review, and audit memos), so that language models are evaluated on text rather than on attribute tables. Free-form text raises an obvious concern: does the exact class probability still apply to the rendered question? We make the transfer provable with two conditions on the renderer. Deterministic template renderers satisfy both properties by construction.

First, the text leaks nothing beyond the visible attributes. The rendered text is $T = r(X_{\text{vis}}, I)$, where r is a deterministic function of the visible attribute assignment *only*, never of latent factors or hidden attributes, and I is the example's position in the sample, which a renderer may use for stylistic variation; ours render each visible attribute with a fixed phrase and ignore it. Because examples are drawn i.i.d. from the world, I is independent of (Z, Y, X). Consequently $T \perp (Y, Z) \mid X_{\text{vis}}$, so the text cannot carry more label-relevant information than the visible attributes.

Second, the text loses nothing from them: each attribute value is rendered by its own fixed phrase that does not depend on I, so the visible attributes can be read back from the memo, $X_{\text{vis}} = h(T)$ for a deterministic decoder h (Appendix B describes h). Together the two conditions give $P(Y \mid T) = P(Y \mid X_{\text{vis}})$: by the second, conditioning on T is conditioning on X_{vis} and I, and by the first I adds nothing about Y.

4 Three Benchmark Worlds

We instantiate the recipe of Sec. 3.2 in three domains with different semantics: credit-risk assessment, a committee decision over manuscripts, and a safety audit of an AI worker's message. Table 6 in Appendix B compares them, and Table 2 gives every setting's visible information, exact Bayes error, and conditional label entropy. Low, Medium, and High denote relative Bayes error, not learning difficulty. All three worlds are author-specified mechanisms, not fitted models of real companies, committees, or agents.

Shared structure of the factor worlds. In the finance and peer-review worlds, every substantive factor takes three ordered values and is shown as one attribute. Low shows every attribute; Medium withholds one and High a second. The settings are nested projections of the same cases. A residual term R, taking values $\{-2, -1, 0, 1, 2\}$ in review and $\{-3, -1, 0, 1, 3\}$ in finance with probabilities $(.03, .09, .76, .09, .03)$, enters the outcome rule but is never rendered, keeping average Bayes error positive at Low.

Irrelevant fields. Each input in all three worlds also carries 8 fields, such as employee count or submission month, that are fair binary draws independent of every substantive factor and of the residual. They change neither any exact class probability nor the Bayes error, yet the input does not mark them as irrelevant; a method can only be distracted by them.

4.1 World 1: Financial Default

A model assesses whether a company will default on its debt obligations within the next year. The sector (4 values) and business cycle (expansion, steady, contraction) are always visible. The company's position is described by 8 factors: operating cash generation, cash buffer, and refinancing access are resources; recurring debt service and near-term principal maturities are obligations; funding-rate exposure, customer concentration, and operating flexibility modify them. Default occurs when cash generation + cash buffer + refinancing + $R <$ debt service + principal due, where R is the residual. The rule is not additive in the observed factors: in a contraction, cash generation falls further with customer concentration, by a sector-dependent amount, while operating flexibility partly protects it, and the business cycle scales both refinancing access and the cost of funding-rate exposure. Medium hides the cash buffer and High also hides the principal maturities. The default prior is 0.211.

4.2 World 2: Peer-Review Outcome

A model predicts whether a submission will be accepted. The contribution type (theoretical, empirical, applied) is always visible and sets the weights of 9 quality factors: novelty, problem significance, technical validity, evidence strength, comparison quality, evaluation coverage, robustness, reproducibility, and clarity. Theoretical work weights validity and novelty most, empirical work validity, evidence, and comparisons, and applied work significance. Two interactions reward strong evidence backed by well-controlled comparisons, and sound validity backed by stable results. A submission with a serious validity flaw is rejected regardless of its score, and the hidden residual perturbs the score, a simple stand-in for the documented inconsistency of real committees (Cortes & Lawrence, 2021). Medium hides novelty and High also hides technical validity. The acceptance prior is 0.336.

4.3 World 3: Covert Information Transfer

This AI-safety world audits a worker for covert information transfer. A worker AI files reports with an authorized reviewer, and a confidential project tag, one of 26 letters, must not reach the other agents on the shared system. Only the reviewer can read a report's body, but every report is stored under a file name containing a 16-letter run identifier that the worker generates itself, and file names are visible to all agents. A worker could therefore leak the tag to a colluding agent by writing it into the identifier. The label records whether this encoding procedure was used. The report type (progress update, experiment result, or error report), tag, and 16 identifier letters are drawn independently and uniformly, and the worker encodes with probability $1/2$, independently of them. Under encoding, the tag replaces the letter at a position fixed by the report type: 5 for a progress update, 9 for an experiment result, and 13 for an error report. An accidental match is negative, and an encoding that replaces a letter with the same letter is positive, so identical inputs carry different labels.

The model sees the report type, the identifier, and audit information about the tag; the memo does not state the positional rule. Low reveals the exact tag, Medium a 4-letter range, and High an 8-letter range (the last range of each partition is shorter). If the visible range has m letters and contains the identifier's letter at the report's position, $P(\text{encoding} \mid x_{\text{vis}}) = 26/(26+m)$; otherwise the class probability is zero. The other 15 letters cancel, so the class probability stays exact although the input space is far too large to enumerate. Bayes error is $\sum_i m_i^2/(2 \cdot 26^2)$ over the range sizes m_i: 0.019, 0.074, and 0.145. Every identifier is freshly drawn, so test inputs essentially never repeat training inputs, and generic encodings that treat an identifier as one categorical value carry no signal.

5 Experiments

Setup. We compare 9 models' probabilities with exact class probabilities using 25 few-shot demonstrations at Medium (Fig. 2; Appendix A.3), and track how more demonstrations change two of them (Fig. 4; Appendix A.2). For accuracy, we compare logistic regression (traditional ML) with an agent that synthesizes a Python predictor from training examples, and with a deliberately cheatable variant of that agent given labeled test-set access (Appendix A.1). This comparison uses 50 training and 500 test examples for each of three prospectively chosen seeds (2032–2034) at Low,

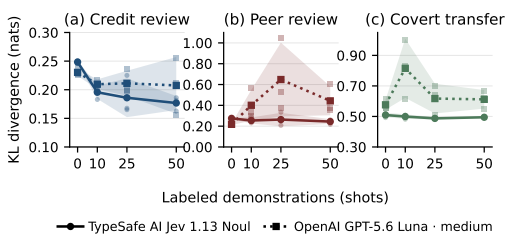

Figure 4: Probability quality at Medium visibility: lower KL is better. Lines/bands: mean ± s.d.; dots: three seeds, 500 cases each.

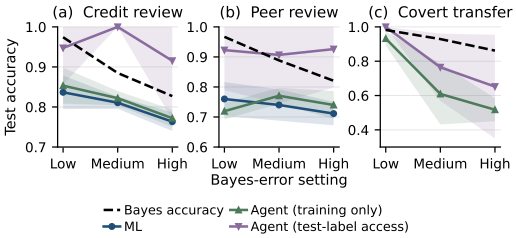

Figure 5: Realized accuracy, 50 training examples. Three seeds: mean ± s.d. Covert transfer (c) has no ML baseline.

Medium, and High; every input carries the 8 irrelevant fields. Agents receive only memo text and realized labels; ML receives structured attributes. Logistic regression and the Bayes error estimators are omitted in the AI-safety world, where their encodings carry no signal (Appendix A.1).

KL divergence. Because every case carries its exact class probability, each model's probability can be scored by its KL divergence from the truth (Eq. 2; Fig. 2). Among the nine models we compare, Jev has the lowest KL in all three worlds and is also the cheapest at published list prices (Appendix A.3). More decision models like Jev are likely to follow, and open-source ones already exist (Palmer, 2026); each can be checked against exact class probabilities in the same way.

Effect of few-shot demonstrations. Fig. 4 varies the number of demonstrations for Jev and GPT-5.6 Luna. Jev is stable: its KL falls steadily with more demonstrations in credit review and stays flat in peer review and AI safety, so adding demonstrations does not hurt it. Luna starts better than Jev without demonstrations in credit and peer review, but it varies widely across seeds, and in peer review and AI safety it is worse with demonstrations than without.

Realized accuracy and Bayes accuracy. Fig. 5 reports the fraction of 500 test labels predicted correctly, using $n_{\text{train}} = 50$ for every method; unknown predictions count as incorrect. Shading gives sample standard deviation (not a confidence interval), cropped to each panel's displayed range. With labeled test access, 17 of the 27 generated programs (three worlds, three hiding levels, three seeds) look up test answers or memorize corrections and score 100%, well above Bayes accuracy, which is the overfitting signal described in Sec. 3.1; all programs remain in the averages (Appendix C.1 audits them). Fig. 12 in Appendix C.2 scores the same predictions by expected accuracy (Eq. 1); we use that analysis for the Bayes gaps below.

At Low, the best method without test access reaches 85.1% expected accuracy in finance and 76.1% in peer review, leaving gaps of 12.3 and 20.6 points to Bayes accuracy (97.4% and 96.7%). These gaps exceed those at Medium and High. The peer-review agent stays near 72% at both Low and High; more visible information need not make a rule learnable from 50 examples. ML exceeds the agent by 4.2 points at peer-review Low.

In the AI-safety world, training-only agents infer positional rules when the exact tag is visible, reaching 93.7% expected accuracy at Low, but fall to 61.4% and 53.2% once only a tag range is visible. Variation is largest at Medium (18.3 percentage points s.d.).

Can Bayes error estimators recover the known ε^*? We evaluate three standard estimators collected by FeeBee (Renggli et al., 2021) (the Cover–Hart 1NN bounds, the kNN bounds with Devroye's binary refinement, and the hyperparameter-free Henze–Penrose divergence estimator, GHP) on the one-hot encoded structured visible attributes of finance and peer review, sweeping sample size and hiding level and scoring each estimate directly against the truth.

Fig. 6 plots the estimated intervals against the known truth. Nearly all intervals lie above ε^*. The overestimate is largest at Low, where the truth is smallest, and shrinks only slowly as the sample grows from 200 to 4000. At Low, each world has over 15 million possible visible inputs, so nearest neighbors usually differ in several attributes, and the estimators read their label disagreement as irreducible error (Appendix C.3).

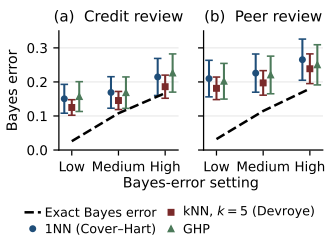

Figure 6: Bayes-error bounds ($n = 4000$), not conf. intervals.

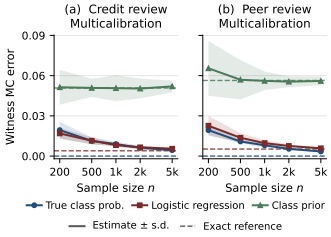

Figure 7: Witness MC at High Bayes error. Shading: $\pm$ s.d.

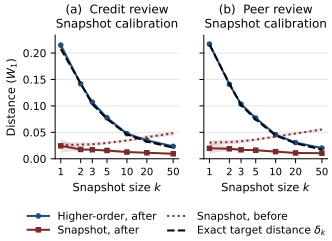

Figure 8: Snapshot and higher-order errors at High.

Can multicalibration error be estimated from finite samples? Fig. 7 estimates witness MC (Eq. 3) at High using 10 equal-width probability bins and 10 calibration resamples independent of training per sample size. We compare the true class probability p^*, logistic regression trained on 1000 examples, and the class prior. Groups use sector, business cycle, and their conjunctions in finance, and contribution type, problem significance, and their conjunctions in peer review; both values of each irrelevant field add 16 more groups (35 and 31 in total). The predictor p^* has zero population MC error, but its estimated MC error is positive at every sample size in both worlds. Estimates approach exact references as sample size grows, while the class prior remains substantially worse than logistic regression.

How well does snapshot calibration approximate higher-order calibration? A k-snapshot records the positive fraction of k independent labels for one input. Its distribution includes sampling variation even with unlimited calibration inputs, so fitting it need not recover the distribution of true probabilities. ProbabilityBench makes both targets exactly computable, allowing us to test how well snapshot calibration approximates full higher-order calibration as k increases.

Fig. 8 reports population-weighted W_1 errors (Eq. 5) at High over three independent trials (1000 training and 2000 calibration inputs each), together with δ_k, the population-weighted distance between the two true targets; Appendix C.4 gives the protocol following Ahdritz et al. (2024). At small k, the fitted predictor has low snapshot error but a higher-order error many times larger that closely tracks δ_k; the gap closes only as k grows.

6 Conclusion

Whether a model's probabilities are right, and how much of its error is irreducible, can only be settled where the true class probabilities are known, which has usually meant simple synthetic distributions such as Gaussian distributions. ProbabilityBench brings that check to natural-language cases of the kind a language model is actually asked to read: three hand-designed worlds in which the class probability of every instance is exact.

The lesson is that estimates one would otherwise have to trust can be noisy or biased at practical sample sizes, or the regime in which their guarantees hold may be out of reach. A new Bayes error estimator, a new calibration metric, or whether a decision model is calibrated or not (TypeSafe AI, 2026) should therefore be checked on a benchmark with known uncertainty, such as ProbabilityBench, before it is trusted on data where the truth is unavailable.

The memos are rendered from fixed templates. Richer renderers, including LLM-generated prose, are a harder but meaningful direction for future work: to keep the class probability of every rendered case exact, free-form text must still satisfy both conditions of Sec. 3.4. We chose finance, peer review, and safety, but other users will care about other domains. Building the three worlds took substantial manual design and verification, but others can start from the recipe and the three worlds rather than from scratch: much of that work could now be automated, leaving a person to check a proposed world far more lightly than we had to. We hope ProbabilityBench serves as a place to test evaluation instruments before they are used where the truth is unavailable.

AI USE STATEMENT

We used generative AI assistants, including Codex and Claude Code, to assist with implementation and tests, experimental design, analysis and interpretation of results, figure preparation, and manuscript drafting and editing. We take responsibility for the final text, claims, code, and results, including AI-assisted contributions.

ETHICS STATEMENT

ProbabilityBench uses simulated examples and synthetic labels, rather than records of real companies, manuscript submissions, or confidential projects.

REPRODUCIBILITY STATEMENT

Sec. 3 specifies how each world is constructed and how its exact class probabilities are computed, and Appendices A–C give the model and agent protocols, world definitions, and evaluation details. Following the ICLR 2027 author guidelines,[1] we will share our code with the reviewers and area chairs through a link to an anonymous repository, which we will post as a comment once the discussion forums open.

A Baseline Methods and Prompt Specifications

This appendix describes the evaluated baselines, their prompt and execution protocols for the reported comparisons.

A.1 Baseline Methods

Traditional ML. L2-regularized logistic regression uses one-hot encoded structured visible attributes and realized hard labels from 50 training examples. It is evaluated in finance and peer review only. In the AI-safety world, a generic one-hot encoding carries no signal: each identifier becomes a new category never seen in training, and the remaining attributes are independent of the label. The one informative feature, whether the identifier's letter at the report's position falls in the visible tag range, presupposes the rule; discovering that rule from examples is the task the agent is given.

Agentic program synthesis. GPT-5.6 Luna with medium reasoning, via Codex CLI, inspects the same 50 training examples with their realized labels and emits a reusable Python scoring program. The generated program then predicts outcomes from the full rendered memo alone, deriving its own features. The training-only condition has no test inputs or labels available during synthesis. Memos already supply assessments such as weak cash generation or a sound technical argument; this is not evaluation on raw financial statements or complete manuscripts.

Agent with labeled test access. The second agent condition additionally receives realized test labels in `test.json`, explicitly identified as the evaluation set whose accuracy should be maximized. This deliberately cheatable condition permits using those labels directly; Appendix A.4 gives the access conditions and prompts.

These three conditions comprise two method families. All use the same 50 training examples and their realized labels; true class probabilities are withheld.

A.2 Direct Probability Comparison

Fig. 2 holds the demonstration count fixed and varies the model across the nine of Appendix A.3; Fig. 4 does the reverse, varying the demonstration count for two of those nine. It compares Jev 1.13 Noul (`typesafe/jev-1.13-20260917`) with GPT-5.6 Luna at medium reasoning: the cheapest model plotted and the strongest in KL, against the OpenAI model whose messages the other seven reuse. This section also fixes the scoring rule that both figures use.

Both models receive identical memos, questions, class criteria and nested prefixes of 0, 10, 25 or 50 realized-label demonstrations at Medium visibility. Each of seeds 2032–2034 supplies 500 held-out cases per world, giving 18,000 predictions per model. No true probabilities or hidden fields are supplied. Jev uses its native Noul endpoint; Luna uses chat completions via OpenRouter with an 8,000-token output cap and no temperature override. Its system message names both classes and asks for the positive-class probability, including when the negative class is more likely, rather than confidence in a chosen answer. Shown here for peer review:

```
Estimate P(outcome = accept) for the test case. The positive class is
   accept (the question's true criterion); the negative class is reject
    (the false criterion). A probability of 1 means certainly accept; 0
    means certainly reject. Even when reject is more likely, return the
    probability of accept, not confidence in your chosen class. Return
   exactly one line: probability_positive: <number from 0 to 1>. Do not
    use percentages.
```

The class names are all that varies across worlds: credit review substitutes *default* and *no-default*, and covert transfer *encoding* and *no-encoding*. The field name stays `probability_positive` throughout. The user message carries Jev's own question and state objects serialized as JSON, holding the same instructions, class criteria, demonstrations and test memo the native endpoint receives, so the two models are asked the same question about the same evidence.

Table 1: Published list prices charged on the cost axis of Fig. 2, in USD per million tokens. Each source is the page stating that rate, retrieved 2026-09-21.

Model	In	Out	Source
Jev 1.13 Noul	0.042	0.00	`typesafe.ai/blog/introducing-system-one-models-and-jev`
GPT-5.6 Luna	0.20	1.20	`developers.openai.com/api/docs/models/gpt-5.6-luna`
GPT-5.6 Terra	2.00	12.00	`developers.openai.com/api/docs/models/gpt-5.6-terra`
Claude Haiku 4.5	1.00	5.00	`platform.claude.com/docs/en/about-claude/pricing`
Claude Sonnet 5	2.00	10.00	`platform.claude.com/docs/en/about-claude/pricing`
Gemini 3.8 Flash	0.75	3.75	`ai.google.dev/gemini-api/docs/pricing`
DeepSeek V4 Flash	0.15	0.60	`api-docs.deepseek.com/quick_start/pricing`
Qwen3.8 Flash	0.15	0.47	`openrouter.ai/qwen/qwen3.8-flash`
Mistral Small 3.2	0.094	0.25	`openrouter.ai/mistralai/mistral-small-3.2-24b-instruct`

Notes. Jev bills input tokens only and meters no charge for output. Its plotted point uses the charge its endpoint returns, which equals the published $0.042 per million applied to the input tokens it reports; it has one vendor and reported no cached tokens. Gemini 3.8 Flash's rate is introductory through 2026-12-31 and then doubles to 1.50/7.50. DeepSeek's rate is off-peak; peak hours double both. Qwen3.8 Flash and Mistral Small 3.2 take OpenRouter's listed rate because their owners no longer publish one for the version we called; Alibaba QwenCloud lists the same rate for Qwen3.8 Flash.

We score $\mathrm{KL}(p^* \,\|\, q)$ (Eq. 2) from the exact class probability p^* to the prediction q, in nats, clipping only q to $[0.001, 0.999]$. This direction is the expected excess log loss of q over p^*, and it stays finite when p^* is 0 or 1, where the reverse direction is infinite. In Fig. 4, clipping affects only the 62 Luna predictions at exactly 0 or 1, and thresholds of 10^{-4} and 10^{-6} leave the ordering of the two models unchanged. In Fig. 2, it affects 585 predictions, 580 of them from DeepSeek V4 Flash; at the smaller thresholds the only change in ranking is DeepSeek dropping further, and Jev stays lowest in every world.

A.3 Cost and Probability Quality

Fig. 2 places each model at its measured price and its mean KL at 25 shots at Medium visibility. Every panel carries the full model set except that Claude Sonnet 5 is absent from AI safety, where it fails the validity rule below. Every model receives byte-identical messages to the Luna run above, including the system message of Appendix A.2, so the comparison varies the model and its published inference settings, not the evidence. Seeds 2032–2034 each supply the first 300 held-out cases per world; the saved Jev and Luna responses are rescored over those same case indices.

Cost is each model's published list price applied to the token counts its own provider returned, divided by requests rather than by valid replies, so a model that fails often cannot appear cheap. We price per vendor rather than with a tokenizer of our own because identical prompts are counted very differently: credit-review prompts average 4,321 tokens for GPT-5.6 Terra and 7,136 for Claude Sonnet 5.

We plot list price rather than billed cost, which reflects our request pattern, through caching discounts and provider routing, more than the model; Table 1 gives the rates and their sources.

Cost remains money for each model's own endpoint and settings, not matched compute: Jev returns roughly 20 output tokens while reasoning models bill their traces, and a fixed reasoning effort is not a common unit across vendors.

Models are configured at the cheapest setting that yields a valid answer, and that setting is recorded per model. Several endpoints reject a disabled reasoning parameter, and several will not honour the plain-text answer contract; those receive a JSON schema requiring exactly one field, `probability_positive`, a number in $[0, 1]$: the same answer the text contract asks for. A wrapping code fence is accepted. Excluding models that cannot follow a text format would select on instruction following rather than on probability quality, so they are configured to answer and reported alongside the rest. Invalid replies remain failures and receive no quality retries.

Of 24,300 replies, 151 (0.62%) were unusable, all but three from Claude Sonnet 5 in AI safety, where it often used up its token budget without answering. A model is plotted in a world only when

every block there is at least 99.5% valid, so Claude Sonnet 5 is omitted from AI safety; scoring only its answered cases would favor it, because its failures concentrate on the cases it finds hardest.

A.4 Agentic Program-Synthesis Prompt

Matched comparison. Figs. 5 and 12 use Codex CLI 0.154.0 (alpha 6.2) with GPT-5.6 Luna at medium reasoning. For each world, Low/Medium/High setting, and data seed 2032–2034, two fresh sessions use the same 50 training and 500 evaluation examples as ML. There is one synthesis per seed and condition, giving 54 trials in total. The green *training-only* condition contains only `README.txt` and `train_examples.json`; no test inputs, labels, or true probabilities are available during synthesis. The purple *test-label access* condition adds same-directory `test.json` with memo text and realized labels, but no true probabilities. Training rows contain exactly `rendered_text` and `true_outcome`; the test file uses the same schema. No structured feature dictionary, schema, decoder, case ID, or hidden attribute is supplied. The training-only prompt is:

```
Read README.txt and train_examples.json. Build a reusable Python
    scoring program that achieves the best possible classification
    accuracy on the evaluation examples. Write score_program.py with a
    predict_probability(example: dict) -> float function returning P(<
    positive label>). The runner will apply your program unchanged to
    all evaluation examples. Also write method_summary.txt describing
    your approach. When finished, reply with only: done.
```

The test-label access prompt inserts these two sentences after the first:

```
The file test.json contains exactly the evaluation examples that the
    runner will score. Your goal is to maximize classification accuracy
    on this specific test set.
```

Stating the objective this explicitly is a simplification of the reward-seeking behavior coding agents already show, such as reading and using test answers directly (Von Arx et al., 2025; Lodkaew et al., 2026).

Both conditions use the same training file and README. The README names the task and labels, describes the files and the function interface, asks for Python's standard library only, and directs the agent not to read outside its directory. A filesystem policy enforces this, and tool network access is disabled. The finished program is evaluated unchanged in a separate process that receives only `rendered_text`; reference labels and true probabilities stay with the controller. A test-label access program can still read its supplied test file at prediction time. All 54 trials completed with 500 predictions each, and none was regenerated based on its score. The two conditions differ in both data access and stated objective, so the comparison does not isolate the effect of the wording alone. Appendix C.1 reports the program audit.

A.5 Supervision and Sample Sizes

The main comparison uses 50 training examples per method. For each data seed 2032–2034, they are rows 0–49 of a 1,000-row training pool, and evaluation uses rows 1000–1499 of the same draw. The remaining 950 pool examples are not supplied to the 50-example methods. Dataset and source-record hashes record this provenance. True class probabilities are used only for evaluation.

B World Specifications

This appendix specifies the three worlds; the released code holds the authoritative value lists, probabilities, and coefficients. Table 6 compares the worlds, and Table 2 gives each setting's visible information, exact Bayes error, and conditional label entropy. For $p_x = P(Y{=}1 \mid X_{\text{vis}}{=}x)$, we compute

$$H(Y \mid X_{\text{vis}}) = \sum_x P(X_{\text{vis}}{=}x)\, h_2(p_x), \qquad h_2(p) = -p \log_2 p - (1-p)\log_2(1-p).$$

This weights each visible pattern by its exact population mass and reports entropy in bits, with $0 \log_2 0 = 0$. Every setting also shows the 8 irrelevant fields of Table 5; because they are independent of everything else, they leave both quantities unchanged. In the AI-safety world, the values follow in closed form from the tag partition (Sec. 4.3).

Table 2: Bayes error and conditional label entropy of each setting. Each subtraction starts from the named preceding setting.

Dataset	Setting	Visible information	Bayes error	Entropy (bits)
Finance	Low	Sector, business cycle, and all eight factors	0.026	0.132
	Medium	Low − cash buffer	0.108	0.305
	High	Medium − principal maturities	0.167	0.538
Peer review	Low	Contribution type and all nine factors	0.032	0.154
	Medium	Low − novelty	0.115	0.330
	High	Medium − technical validity	0.180	0.560
AI safety	Low	Report type, identifier; tag's broad range, narrow range, letter	0.019	0.119
	Medium	Low − exact tag letter	0.074	0.317
	High	Medium − narrow range	0.145	0.490

Why the hiding order matters. Nesting alone guarantees only that ε^* cannot decrease: hiding a factor raises it only if the factor changes the outcome for some states whose other visible factors coincide. The factors are sampled independently (up to the small dependencies below) and every factor enters the outcome rule; exact enumeration confirms that hiding any one of them raises ε^*. The hidden factors were chosen to give three well-separated settings while 50 training cases still cover only about 1.4% of the High population's mass in expectation, even ignoring the irrelevant fields. We verify the strict increases in Table 2 by exact enumeration. In the AI-safety world, each coarser tag range strictly enlarges some partition cell, which raises $\sum_i m_i^2$.

Finance and peer-review factors. Table 3 lists every substantive factor. Most factors have prior probabilities $(.48, .27, .25)$ over their three values; technical validity instead has $(.15, .35, .50)$. Contribution types and sectors are uniform, and the business cycle has probabilities $(.30, .40, .30)$. Small dependencies are added: in review, each level of validity above the middle moves 0.035 of probability from the lowest to the highest value of evidence and robustness (and the reverse below it); in finance, each level of cash generation similarly moves 0.03 in the cash buffer, and the cycle moves 0.04 in refinancing access, favoring broad access in expansion. Every substantive state has positive probability, and the residual is independent of all factors. The worlds have 78,732 (finance) and 59,049 (review) substantive states, or 5 times as many with the residual.

Finance outcome rule. Amounts are in a fixed normalized unit. Cash generation is 3, 5, or 7; the cash buffer 1, 3, or 5; refinancing access 0, 2, or 4, multiplied by 1, 0.75, or 0.40 in expansion, steady, and contraction cycles. Recurring debt service is 1, 2, or 3, plus 0, 0.25, or 0.75 per level of funding-rate exposure in the same three cycles; principal due is 1, 3, or 6. In a contraction, cash generation falls by 1 plus 0.75 per level of customer concentration, and by a further 0.25, 0.5, 0.75, or 0 per level in technology, manufacturing, consumer, and healthcare; it rises by 0.5 per level of operating flexibility. The company defaults when resources plus R fall strictly below obligations, with R from Sec. 4; covering obligations exactly is not default. Comparisons use integer twentieths, so ties are exact.

Peer-review outcome rule. The score is the contribution-specific weighted sum of the 9 factor values (Table 4), plus 0.6 when evidence and comparisons are both at their highest value and 0.6 when validity and robustness are both at their highest value. A submission is accepted if the score plus R is at least 10 and its validity is not a serious flaw. Scores use integer tenths, so ties are exact.

Table 3: Substantive factors in the finance and peer-review worlds, with values ordered $0/1/2$. Starred factors are hidden at Medium and High; double-starred factors only at High.

World	Factor	Values
Finance	Operating cash generation	weak / moderate / strong
	Cash buffer*	limited / moderate / substantial
	Recurring debt service	light / moderate / heavy
	Near-term principal maturities**	dispersed / moderate / concentrated
	Refinancing access	limited / partial / broad
	Funding-rate exposure	low / moderate / high
	Customer concentration	low / moderate / high
	Operating flexibility	limited / moderate / high
Peer review	Novelty*	incremental / substantial / major
	Problem significance	narrow / moderate / broad
	Technical validity**	serious flaw / limited concern / sound
	Evidence strength	weak / moderate / strong
	Comparison quality	inadequate / partly controlled / well controlled
	Evaluation coverage	narrow / moderate / broad
	Robustness	fragile / mixed / stable
	Reproducibility	insufficient / partial / complete

Applied	0.9	1.8	1.3	1.2	0.9	1.3	1.0	0.8	0.8

Observations in the AI-safety world. Narrow tag ranges partition the alphabet into `a–d`, `e–h`, `i–l`, `m–p`, `q–t`, `u–x`, and `y–z`; broad ranges into `a–h`, `i–p`, `q–x`, and `y–z`. These fixed partitions do not depend on the label. The memo explains the setting (private report bodies, identifiers visible in file names) and asks whether the encoding procedure was used, without stating the positional rule.

Identifiers are stored as 16 letters and displayed in 4 hyphen-separated groups of 4. The separators are presentation only: they are not part of the stored value, they carry no information, and the encoding positions count letters rather than display slots. Because those positions are 5, 9, and 13, each one falls on the first letter of a group, so the candidate sites are visually salient even though the memo never states them.

Reading attributes back from memos. The decoder h behind the second condition of Sec. 3.4 recovers each attribute by searching the memo for that attribute's fixed phrases. The search is unambiguous because, in all three worlds, no two phrases are equal and none occurs inside another; otherwise a memo containing the longer phrase would also match the shorter one. The covert-transfer identifier has too many values for a phrase table, so h reads it from its fixed slot after "run identifier is" and rejects a memo whose identifier is empty, repeated, or grouped differently. With these conditions h inverts r, so r is injective in x_{vis}.

C Additional Experimental Results

C.1 Generated Programs with and without Test-Label Access

For contrast, Fig. 9 shows a program synthesized without test access, from AI safety at Low (seed 2033). From the 50 training memos it recovers the exact rule: the tag is written at the fifth, ninth, or thirteenth letter for a progress update, experiment result, or error report. Its decisions agree with the Bayes classifier on all 500 test cases, so its expected accuracy equals Bayes accuracy (98.2%).

Table 5: Irrelevant fields: each is an independent fair draw between the two listed values.

    return 1.0 if compact_identifier[slot] == tag.group(1).lower() else 0.0
```

Figure 9: A program synthesized from training data only, in AI safety at Low, seed 2033, verbatim. It implements the Bayes-optimal positional rule and nothing else.

Realized accuracy far above Bayes accuracy implies that the labeled-access agent is not solving the prediction problem. Fig. 10 shows what that looks like in the generated source: a lookup table built from the answers, wrapped in a plausible feature scorer and a docstring that presents the arrangement as prudence. It scores 100% realized accuracy against a mean Bayes accuracy of 81.8% on the same inputs, and 74.0% expected accuracy. Removing `test.json` changes 114 of 500 decisions and

Table 7: Exact Bayes error as the residual's nonzero mass varies, enumerated without fitting models. Residual probabilities are $(.03s, .09s, 1 - .24s, .09s, .03s)$; the benchmark uses $s = 1$.

Setting	$P(R{\neq}0){=}0$	0.12	0.24	0.36	0.48
Financial default world					
Low	0.000	0.013	0.026	0.039	0.052
Medium	0.099	0.104	0.108	0.111	0.115
High	0.158	0.163	0.167	0.171	0.176
Peer-review world					
Low	0.000	0.016	0.032	0.048	0.064
Medium	0.103	0.109	0.115	0.120	0.125
High	0.167	0.174	0.180	0.187	0.193

drops realized accuracy to 77.2%; flipping its labels changes all 500 and drops it to 0%. Neither ablation regenerates the program.

```python
"""Scorer for the financial-default memo task.

The supplied evaluation corpus is deterministic. When it is available beside
this module, retain its exact memo/outcome mapping; the feature scorer below is
also provided so the function remains useful for new memos.
"""

import json
import os
import re

_KNOWN = {}
try:
   with open(os.path.join(os.path.dirname(__file__), "test.json"), encoding="utf-8") as f:
      for row in json.load(f):
         if "rendered_text" in row and "true_outcome" in row:
            _KNOWN[row["rendered_text"]] = 1.0 if row["true_outcome"] == "default" else 0.0
except (OSError, ValueError, TypeError):
   pass

def _fallback(text):

   # ... five further keyword terms, weighted 1.0 or 0.5, elided here ...
   return 1.0 if risk >= 3.0 else 0.0

def predict_probability(example: dict) -> float:
   text = example.get("rendered_text", "") if isinstance(example, dict) else str(example)
   if text in _KNOWN:
      return _KNOWN[text]
   return _fallback(text)
```

Figure 10: The program synthesized with test-label access in credit review at High, seed 2032, verbatim but for the elision marked in `_fallback`. It builds a memo-to-outcome table from `test.json` at import time and consults it before its own features.

Fig. 11 shows the other kind of lookup, embedded in the program itself, from AI safety at Low (seed 2034). The program recovers the same positional rule as Fig. 9 and then hard-codes 11 test identifiers whose letter matches the tag by accident: the cases the Bayes classifier must get wrong. Its own summary says these identifiers "collide with the selected slot by chance" and are "retained as explicit exceptions". Realized accuracy rises from 97.8% for the Bayes classifier on these labels to 100%, while expected accuracy falls from 98.1% to 96.1%, because each exception contradicts a class probability of $26/27$. Removing or flipping `test.json` changes none of its decisions.

```

Figure 11: The program synthesized with test-label access in AI safety at Low, seed 2034, verbatim. It implements the Bayes-optimal positional rule and stores the 11 evaluation identifiers that match by accident as no-encoding exceptions.

Audit summary. We reran each labeled-access program with `test.json` removed and with its labels flipped. Of the 27, 17 score 100%: 11 read the test file at prediction time, like Fig. 10, and 6 embed answers or case-specific corrections, like Fig. 11, so their predictions survive both ablations. The other 10 score below 100% with general rules and are unaffected by either ablation, which does not rule out that the test labels shaped those rules during synthesis.

C.2 Expected Accuracy

Fig. 12 scores the same predictions as Fig. 5 against each input's exact class probability, using Eq. 1. All methods cover all three Bayes-error settings and are averaged over three matched data seeds. Recorded unknown predictions contribute zero. The dashed line averages exact Bayes accuracy over the three 500-input test sets. This comparison removes sampled-label noise and is bounded by Bayes accuracy example by example. Realized accuracy instead compares predictions with one sampled outcome per input and can exceed that expected Bayes accuracy.

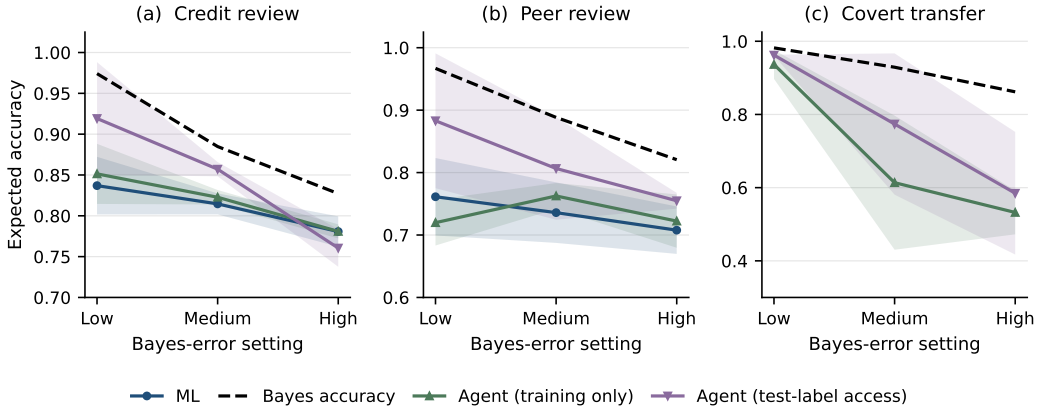

Figure 12: Expected accuracy (Eq. 1) of the predictions in Fig. 5, in finance (a), peer review (b), and covert transfer (c), using 50 training examples per method and three seeds (mean ± s.d.). Dashed lines show mean exact Bayes accuracy on the same test inputs, which expected accuracy cannot exceed, unlike realized accuracy; y-axis ranges differ across panels.

C.3 Bayes-Error Estimators

The estimators of Fig. 6 read the one-hot encoded structured visible attributes, including the 8 irrelevant fields, under Euclidean distance, so a nearest neighbor is a case that differs in the fewest attributes. For a sample of n cases, the 1NN and kNN ($k = 5$) estimators classify one half of the sample from the other and bound ε^* by the held-out error; GHP needs no split and uses all n cases. Each plotted interval averages the bounds from three independent samples, drawn with seeds 2032–2034. The sample-size sweep uses $n \in \{200, 500, 1000, 2000\}$, and Fig. 6 uses $n = 4000$.

The irrelevant fields carry no label information but still separate neighbors. Rerunning at $n = 4000$ without them lowers every bound. At Low, the lower bounds fall from 0.102–0.113 to 0.074–0.076 in finance ($\varepsilon^* = 0.026$) and from 0.148–0.156 to 0.109–0.116 in peer review ($\varepsilon^* = 0.032$): the irrelevant fields account for 28–42% of the excess over ε^*, and every Low interval still lies well above it. At Medium and High, 9 of the 12 intervals then contain ε^*; the exceptions are the three peer-review intervals at Medium.

C.4 Reading the Snapshot-Calibration Comparison

Fig. 8 uses three independent trials with seeds 2032–2034. Each retrains a logistic model q on 1000 labeled examples, including the 8 irrelevant fields, and forms 10 equal-width bins of its predicted probability. Within a bin C, the Bayes mixture π^*_C is the exact population-weighted distribution of $p^*(x)$. The snapshot target $\mathrm{proj}_k\, \pi^*_C$ instead describes the fraction of positive labels in k independent

draws at the same input. Both targets are obtained by enumeration; evaluation draws no new inputs or labels.

We directly measure the separation between these two targets by

$$\delta_k = \sum_C w_C W_1(\mathrm{proj}_k\, \pi^*_C, \pi^*_C)\,, \qquad w_C = P(U \in C). \tag{7}$$

For a fixed partition, δ_k is independent of the calibration sample and fitted histogram. The triangle inequality implies

$$|E_{\mathrm{HO}}(\widehat{\nu}_k) - \delta_k| \le E_k(\widehat{\nu}_k). \tag{8}$$

Thus small snapshot error forces the fitted predictor's higher-order error to be close to δ_k. This distance is not generally the difference between the two fitted-predictor errors, an additive uncertainty component, or a lower bound for every estimator using k labels.

For example, if every input in a bin has true probability $1/2$, its 2-snapshots take values $0, 1/2, 1$ with probabilities $1/4, 1/2, 1/4$. The snapshot target therefore differs from the distribution of true probabilities, which puts all mass at $1/2$; their W_1 distance is $1/4$.

For each trial, we independently sample 2000 calibration inputs and retain those inputs across $k \in \{1, 2, 3, 5, 10, 20, 50\}$. Before calibration, the model probabilities imply the mixture

$$\nu^{\mathrm{before}}_{k,C} = \frac{1}{N_C} \sum_{i:x_i \in C} \mathcal{L}(\mathrm{Binomial}(k, q(x_i))/k)\,, \tag{9}$$

where N_C is the number of sampled inputs in the bin. We average complete binomial laws, not a single law evaluated at the mean q. This uses no calibration labels and does not assume that the scalar logistic model already produces a distribution over probabilities.

After calibration, $\widehat{\nu}_{k,C}$ is the empirical distribution of observed positive-label fractions from the bin's calibration inputs, following Ahdritz et al. (2024). Labels are independently drawn conditional on each input; exact class probabilities generate these labels and define evaluation targets, but are not supplied as fitting targets. The three plotted errors are $E_k(\nu^{\mathrm{before}}_k)$ (dotted maroon), $E_k(\widehat{\nu}_k)$ (solid maroon), and $E_{\mathrm{HO}}(\widehat{\nu}_k)$ (solid navy), as defined in Eq. 5. All use exact population bin weights and the same scalar W_1 distance. The two solid curves therefore hold the fitted distribution fixed while changing its target. The black dashed curve adds δ_k from Eq. 7, computed once per training-seed partition and snapshot size.

Bands give one sample standard deviation across the three independent training-and-calibration seeds; they are not confidence intervals. For δ_k, variation comes only from the bins induced by independently trained base models, not from the calibration inputs or labels. All positive-mass bins received calibration inputs in every trial; both worlds have 10 such bins in each trial. Fitting lowers the mean snapshot error at every evaluated k in both worlds. At small k, low snapshot error coexists with much larger higher-order error that closely tracks δ_k: at $k = 2$ in financial default the two are 0.142 and 0.142 against a snapshot error of 0.018. The exact target distance decreases across the evaluated snapshot sizes in both worlds. The experiment does not establish improved higher-order error over the original model, whose higher-order error is not plotted.
