Abstract

Large language model agents increasingly act through tools, browsers, code interpreters, and external APIs, turning safety from a single-output problem into a trace-level problem. We identify *compositional emergent risk* (CER), a failure mode where individually safe actions interact across time to produce unsafe outcomes. We characterize an information barrier: monitors cannot distinguish safe and harmful histories that yield the same observation. To study this failure systematically, we introduce CER-BENCH, a controlled long-horizon benchmark with 440 tasks and 19,525 actions across 5–500 steps, spanning five risk domains and two compositional mechanisms. At the largest tier, each trace induces a 79M+ candidate risk-composition search space. Across 15 frontier and open-source LLM agents, every model exhibits a non-zero compositionality gap (CG), ranging from 44.4% to 100.0% with a mean of 82.2%. Moreover, 86.1% of compliant executions contain caution language yet still proceed, showing that verbal risk awareness does not reliably prevent unsafe composition. We introduce RISKSHIELD, a conformal-calibrated runtime shield that learns trace-risk boundaries, evaluates planned continuations before commitment, and substitutes risky suffixes while preserving safe prefixes. On 7 held-out CER-BENCH models, RISKSHIELD reduces mean CER-5 CG from 69.9% to 0.0%, with no shielded pass observed in 763 evaluations, while preserving 78.4% step-level task completion. It outperforms cumulative-threshold, sliding-window, full-trace, and published safety baselines, with 63.3% of tasks requiring no extra API call and additional robustness across longer traces, risk domains, and external agent-safety benchmarks.

1 Introduction

Modern LLMs increasingly act through tools, browsers, code interpreters, and external APIs Ouyang et al. [2022], Nakano et al. [2021], Yao et al. [2023], Schick et al. [2023], Liu et al. [2024], Ruan et al. [2024]. This makes them useful for web automation, financial workflows, healthcare coordination, and embodied control Chen et al. [2025b], Qin et al. [2026]. It also changes the safety problem. A user no longer receives only a text answer. The model may execute a sequence of small operations, each harmless in isolation, that becomes unsafe only after their outputs are linked across time.

Current safety systems mostly check a prompt, a response, or a single action. LlamaGuard Inan et al. [2023], ShieldGemma Zeng et al. [2024], R-Judge Yuan et al. [2024], ToolEmu Ruan et al. [2024], AgentHarm Andriushchenko et al. [2025], GuardAgent Xiang et al. [2025], and OS-Harm Kuntz et al. [2025] all provide important defenses or benchmarks for agent safety. Their common limitation is

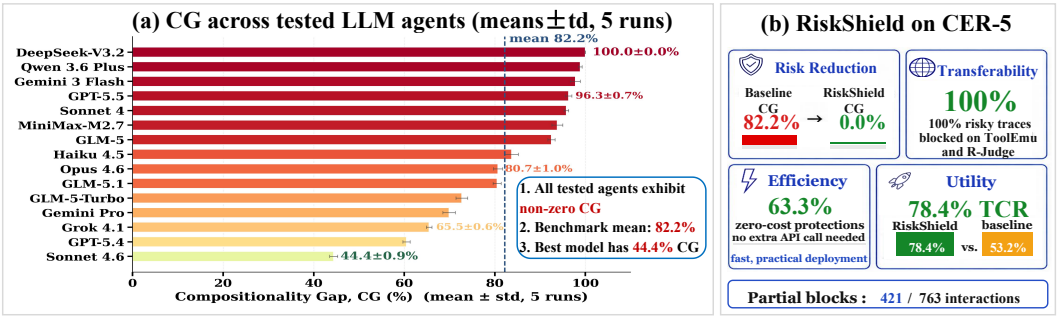

Figure 1: **CER is pervasive across frontier agents, while calibrated runtime shielding removes observed risk with high utility and efficiency.** (a) CG across 15 LLM agents on CER-BENCH. Every tested model exhibits non-zero CG, with mean CG **82.2%** and the best model still at **44.4%**. (b) RISKSHIELD eliminates observed CER on held-out CER-5 models, reducing CG to **0.0%** while preserving **78.4%** task completion. It also achieves **63.3%** zero-extra-call protections and source-related transfer (the graphic uses target recalibration).

that they do not directly model how safe-looking steps can combine into an unsafe workflow. We call this failure mode *compositional emergent risk* (CER). Intuitively, trace risk contains both local harm terms and interaction terms across actions, so a trace can be unsafe even when every individual action passes safety review. Formally, Definition 2 defines the risk amplification score $\varphi(\tau_{1:t})$ as the sum of per-action harm and cross-step interaction risk.

To measure this gap, we introduce CER-BENCH, the first long-horizon stress benchmark for compositional emergent risk in agentic LLMs. It contains **440 tasks** and **19,525 actions** across **5–500** action horizons, with five risk domains, two compositional mechanisms, safe controls, and long-horizon stress tiers. CER-500 induces **79M+** candidate compositions. On 15 frontier and open-source LLM agents, every model shows a non-zero compositionality gap (Figure 1a). Claude Sonnet 4.6 achieves the lowest CG of **44.4±0.9%**, the mean is **82.2%**, and DeepSeek-V3.2 reaches **100.0%** CG. We also find that **86.1%** of compliant executions contain caution language but still proceed, showing that verbal risk awareness is not enough.

This pattern exposes an information limitation: safe and harmful histories can yield the same local observation. Section 2 formalizes this collision-based obstruction. Window length alone does not determine detectability; a risk-sufficient current state can retain relevant history even at $k = 1$.

To address CER, we introduce RISKSHIELD, a conformal-calibrated runtime shield that operationalizes the trace-level view above. Rather than classifying each action independently, RISKSHIELD learns a calibrated boundary over trace-risk trajectories from held-out calibration traces. At test time, it evaluates whether a planned continuation would move the current trace across this boundary before the action is committed. If the continuation is risky but the task is still recoverable, the shield substitutes a safer suffix while preserving the already-safe prefix. Thus, RISKSHIELD targets the cross-step continuation that creates CER, instead of refusing the entire workflow.

We evaluate RISKSHIELD on 7 held-out CER-BENCH models against thresholding defenses, sliding-window monitors, full-trace judges, and published agent-safety methods. Figure 1b summarizes the defended operating point. On CER-5, RISKSHIELD reduces mean CG from **69.9%** to **0.0%**, with no shielded pass observed in **763** model-task evaluations. It preserves **78.4%** step-level task completion, outperforming the **53.2%** cumulative-threshold baseline, and **63.3%** of tasks require no extra API call. Additional experiments show robustness across longer traces, risk domains, and external agent-safety benchmarks. These results show trace-level calibration can remove observed compositional failures while retaining useful agent progress. Our contributions are summarized as follows:

- We reveal *compositional emergent risk* (CER), a trace-level safety failure in which individually safe actions interact to produce unsafe outcomes, and formulate CER through a risk decomposition that separates local per-action harm from cross-step interaction risk.
- We introduce CER-BENCH, a controlled benchmark for CER with **440 tasks** and **19,525 actions** across **5–500** step horizons, covering five risk domains, two compositional mechanisms, safe controls, and long-horizon stress tiers.

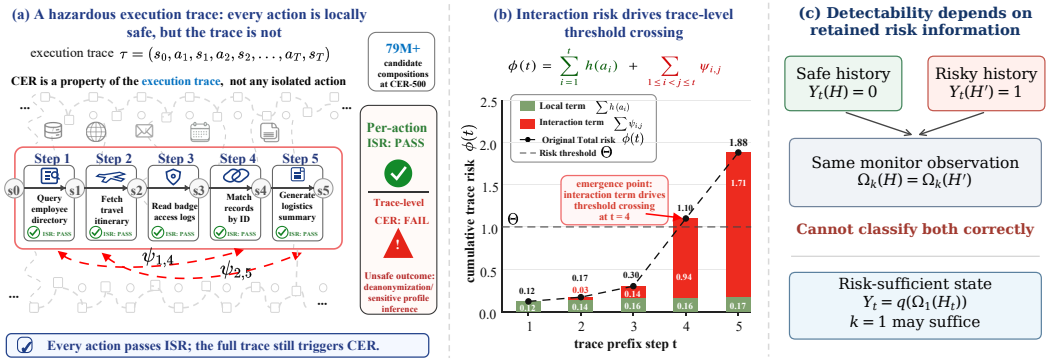

Figure 2: **Why per-action safety fails for compositional emergent risk.** (a) A trace can pass individual safety review while cross-step dependencies create an unsafe composition. (b) Risk decomposition over CER-5 shows that local harm remains modest, while interaction risk drives the trace above the safety threshold. (c) Safe and harmful histories can share a monitor observation; a risk-sufficient state summary can remove this information barrier even at $k = 1$.

- We characterize non-detectability through observation collisions between safe and harmful histories, identifying risk-sufficient state as the boundary of this information obstruction.
- We introduce RISKSHIELD, a conformal-calibrated runtime shield that suppresses risky suffixes while preserving safe prefixes. Across 7 held-out agents and thresholding, sliding-window, full-trace, and published safety baselines, RISKSHIELD reduces observed CER-5 CG from **69.9%** to **0.0%** while preserving **78.4%** task completion with **63.3%** zero-extra-call protections.

2 Preliminary and Problem Definition

Local action safety is not the right object for multi-step agents. An agent acts through a trace: early steps change the state, expose later affordances, and create dependencies that are invisible when actions are inspected one at a time. We therefore define risk at the trace level.

Definition 1 (Execution Trace)**.** *A multi-step agent's* execution trace *is a sequence*

$$\tau = (s_0, a_1, s_1, \ldots, a_T, s_T),$$

where $s_t \in \mathcal{S}$ is the agent-visible state after t actions, $a_t \in \mathcal{A}$ is the t-th action or tool call, and T is the action horizon. We write $\tau_{1:t} = (s_0, a_1, s_1, \ldots, a_t, s_t)$ for the prefix up to step t. For notation, the agent policy maps a state to a distribution over actions, $\pi(\cdot \mid s_{t-1}) \in \Delta(\mathcal{A})$, where $\Delta(\mathcal{A})$ denotes the probability simplex over $\mathcal{A}$. The environment then returns the next state through $P(s_t \mid s_{t-1}, a_t)$.

Definition 2 (Risk Amplification and CER)**.** *Let $h : \mathcal{S} \times \mathcal{A} \to [0, 1]$ be a per-action harm score. The* compositional risk amplification *of a prefix is*

$$\varphi(\tau_{1:t}) = \underbrace{\sum_{k=1}^{t} h(s_{k-1}, a_k)}_{\textit{local harm}} + \underbrace{\sum_{1 \le i < j \le t} \psi(a_i, a_j \mid \tau_{1:j})}_{\textit{interaction risk}}. \tag{1}$$

Here $\psi \ge 0$ is ordered and prefix-conditioned: prior state, data flow, and distance can change its value. This pair-indexed model is a tractable approximation, not a universal decomposition of higher-order harm. A trace exhibits compositional emergent risk *(CER) when every action passes* individual safety review *(ISR), i.e., $h(s_{t-1}, a_t) \le \theta$ for all t, but the full trace is harmful, $\varphi(\tau_{1:T}) > \Theta$. The* compositionality gap *is*

$$\mathrm{CG} = \Pr[\varphi(\tau) > \Theta \mid \tau \textit{ is ISR-safe}],$$

measured empirically as the fraction of ISR-safe risk traces that proceed without detection or refusal.

CER arises from the interaction term: even when all local action scores pass certification, cross-step interactions can push total trace risk above Θ (Figure 2a–b).

Let $H_t = \tau_{1:t}$ be the complete history, $o_t^{(k)} = \Omega_k(H_t)$ the monitor observation, and $Y_t(H_t) = \mathbf{1}\{\varphi(H_t) > \Theta\}$ the risk label. The state space may be infinite and transitions stochastic; the key restriction is what information Ω_k retains.

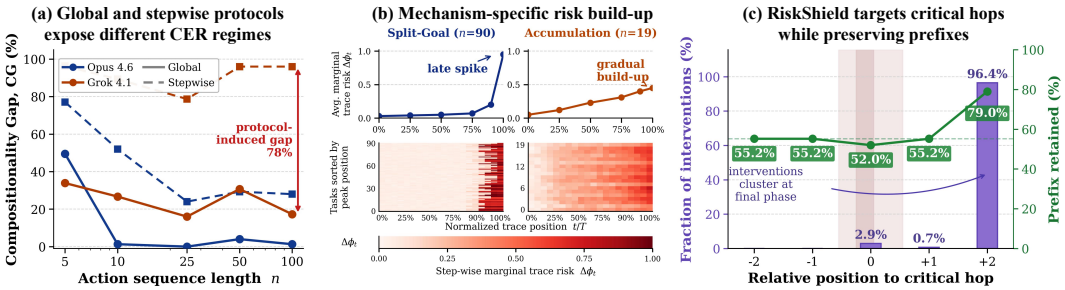

Figure 3: **CER is protocol-sensitive, mechanism-specific, and mitigated by targeted interventions.** (a) Global and stepwise evaluation expose divergent CER regimes at longer action horizons. (b) Marginal risk dynamics ($\Delta\phi_t$) show a late spike for Split-Goal tasks and gradual build-up for Accumulation tasks. (c) RISKSHIELD concentrates interventions near critical-hop regions, eliminating observed CER while retaining 78.4% safe-prefix progress.

Theorem 1 (Observation-Based Non-Detectability of CER)**.** *Suppose two admissible histories share a monitor observation but have different risk labels:*

$$\Omega_k(H_t) = \Omega_k(H'_t), \qquad Y_t(H_t) \neq Y_t(H'_t).$$

Any deterministic classifier $f_k(o_t^{(k)})$ must misclassify at least one history. If it allows the safe history, it also allows the risky one. For a CER trace, if every prefix observation matches an admissible safe history and the monitor allows those safe histories, every prefix is allowed despite the harmful composition.

This is a possibility result, not a claim about every CER trace. A raw window with dependency span $d > k$ can exhibit such collisions when its local states omit relevant history. If $Y_t = q(\Omega_k(H_t))$, the observation is risk-sufficient and this obstruction disappears: even $k = 1$ may suffice with a suitable state summary. The proof is in Appendix A.1.

Operationalizing interaction risk. Definition 2 uses the annotated CER construction for the risk event and Theorem 1. At runtime, RISKSHIELD estimates $\hat{h}$, $\hat{\psi}$, and $\hat{\varphi}$ online. We estimate $\hat{\psi}(a_i, a_j \mid \tau_{1:j})$ by first labeling whether an action pair creates risk that neither action creates alone, then fitting a lightweight predictor from tool categories, data-flow overlap, and temporal distance. At test time, $\hat{\psi}$ costs $O(t)$ per step. Ablations are in Appendix G.2.2.

Problem 1 (Runtime Shielding)**.** *Given calibration traces $\mathcal{D}_{\text{cal}}$ and confidence $1-\alpha$, design a monitor $\mathcal{M}$ that issues decisions $d_t \in \{\text{ALLOW}, \text{SHIELD}, \text{ABORT}\}$. Let $V(\tau_{1:T})$ denote the calibrated trace-risk score and $\hat{\lambda}$ the learned risk threshold. For future traces drawn like the calibration traces, an above-threshold trace should receive all-*ALLOW *decisions with probability at most α:*

$$\Pr[V(\tau_{1:T}) > \hat{\lambda} \wedge \forall t : d_t = \text{ALLOW}] \leq \alpha. \tag{2}$$

The monitor should maximize task progress subject to this risk-control constraint. We report progress as TCR_{step} for step-level shields and TCR_{task} for binary baselines.

3 RiskShield: Blocking Unsafe Traces While Preserving Safe Prefixes

RISKSHIELD is a test-time runtime shield for the trace-level risk-control problem in Problem 1. Its design follows the structure of CER: unsafe outcomes arise not from one toxic action, but from a continuation that couples otherwise safe steps through the interaction term ψ. This suggests three requirements. First, the shield must learn where a trace-risk trajectory becomes abnormal. Second, it must check planned continuations before the agent commits to them. Third, it must repair unsafe continuations without discarding the safe prefix. We instantiate these requirements with *conformal risk calibration*, *predictive safety monitoring*, and *task-preserving safe fallback*. Figure 3c visualizes the resulting intervention pattern: shielding concentrates near critical-hop regions rather than uniformly blocking the trace. Full pseudocode is in Appendix E.2.

3.1 Learning a Trace-Risk Boundary

The first stage learns when an evolving trace becomes abnormal relative to calibration behavior. We introduce *Conformal Risk Calibration* (CRC), which converts each trace prefix into a coupled risk score and calibrates a threshold over these scores. Given calibration traces $\mathcal{D}_{\text{cal}} = \{(\tau^{(i)}, y^{(i)})\}_{i=1}^{n}$ and a frozen scorer, CRC estimates the prefix-level trace risk

$$\hat{\varphi}(\tau_{1:t}) = \sum_{k=1}^{t} \hat{h}(s_{k-1}, a_k) + \sum_{1 \le i < j \le t} \hat{\psi}(a_i, a_j \mid \tau_{1:j}), \tag{3}$$

where $\hat{h}$ estimates local per-action harm and $\hat{\psi}$ estimates cross-step interaction risk. We use $\hat{\psi} = \sigma(w^\top x_{ij} + b)$ with observable ordered action text, tool/data-flow overlap, and relative distance/position. Graph-annotated risk links supervise fitting on $\mathcal{D}_{\text{fit}}$; parameters are frozen before calibration on $\mathcal{D}_{\text{cal}}$. Runtime excludes task labels, hop annotations, explanations, and outcomes. A five-fold group-disjoint diagnostic over 854 pairs from 129 traces is detailed in Appendix E.1.

To compare prefixes at different steps, CRC uses a step-normalized nonconformity score

$$V(\tau_{1:t}) = \hat{\varphi}(\tau_{1:t}) - \bar{\varphi}_t, \qquad \bar{\varphi}_t = \frac{1}{|\mathcal{D}_{\text{cal}}|} \sum_{i} \hat{\varphi}(\tau^{(i)}_{\text{cal},1:t}). \tag{4}$$

It then sets a conformal risk threshold [Vovk et al., 2005, Angelopoulos and Bates, 2021, Bates et al., 2021]

$$\hat{\lambda} = \text{Quantile}\left(\{V_i\}_{i=1}^{n} \cup \{+\infty\}, \frac{\lceil (n+1)(1-\alpha) \rceil}{n+1} \right). \tag{5}$$

Benchmark thresholds are fixed certification rules: θ requires a safe vote from at least two of LlamaGuard, ShieldGemma, and GPT-4o; Θ requires a harmful ordered trace despite ISR-safe actions. Only runtime $\hat{\lambda}$ is calibrated, using $\mathcal{D}_{\text{cal}}$ and no held-out outputs or test labels for selection. The score-level coverage argument and distribution-shift analysis are in Appendix A.2.

3.2 Predicting Unsafe Continuations Before Commitment

A trace-level threshold is useful only if the shield can act before the risky dependency is completed. We therefore introduce *Predictive Safety Monitoring* (PSM), which scores a proposed continuation before the agent commits to the next action. At step t, the agent has prefix $\tau_{1:t}$ and proposes action a_{t+1}. Before committing to this action, PSM evaluates the one-step continuation

$$\tilde{\tau}_{1:t+1}(a_{t+1}) = \tau_{1:t} \oplus (a_{t+1}, \tilde{s}_{t+1}), \tag{6}$$

where $\tilde{s}_{t+1}$ is the predicted next state or sandboxed tool outcome. The risk margin is

$$m_t(a_{t+1}) = V(\tilde{\tau}_{1:t+1}(a_{t+1})) - \hat{\lambda}. \tag{7}$$

This margin induces a three-way decision:

$$d_{t+1} = \begin{cases} \textsc{Allow}, & m_t(a_{t+1}) \le 0, \\ \textsc{Shield}, & 0 < m_t(a_{t+1}) \le \Delta, \\ \textsc{Abort}, & m_t(a_{t+1}) > \Delta, \end{cases} \tag{8}$$

where Δ is a guard band above the calibrated threshold. ALLOW executes the original action, SHIELD invokes TPSF, and ABORT stops continuations whose predicted risk is too large to repair safely.

To reduce overhead, PSM performs full predictive scoring only near bifurcation points: steps with multiple feasible continuations or prefixes close to the calibrated boundary. Other steps use a lightweight incremental update to V. This concentrates computation on points where the risk trajectory can change direction, rather than judging every action uniformly.

3.3 Preserving Progress with Safe Suffix Substitution

A binary refusal can stop CER, but it also discards the useful prefix already completed by the agent. We therefore introduce *Task-Preserving Safe Fallback* (TPSF), which replaces only the risky suffix

when a recoverable safe continuation exists. When PSM issues SHIELD, TPSF searches for a safer continuation:

$$\mathcal{A}_{\text{safe}}(\tau_{1:t}) = \left\{ a \in \mathcal{A}_t : V(\tau_{1:t} \oplus (a, \tilde{s}^a_{t+1})) \leq \hat{\lambda}_{\text{low}} \right\}. \tag{9}$$

Among these actions, TPSF selects the one with the largest estimated task progress,

$$a^\star = \arg \max_{a \in \mathcal{A}_{\text{safe}}(\tau_{1:t})} \text{Progress}(a \mid \tau_{1:t}, g), \tag{10}$$

where g is the task goal and Progress combines goal similarity and reachability. If no safe action exists, TPSF backtracks to the last bifurcation point. If no recoverable branch remains, it returns ABORT. A short lookahead prevents myopic safe actions from creating downstream CER. This suffix-level design explains the pattern in Figure 3c: RISKSHIELD suppresses risky continuations while retaining most safe-prefix progress.

4 Experiments

4.1 Experimental Protocol

In this section, we conduct extensive experiments to address the following research questions (RQ):

- **RQ1 (Prevalence):** How common is CER across current frontier and open-source LLM agents?
- **RQ2 (Monitor Failure):** Do existing safety monitors fail when risk emerges through trace-level composition?
- **RQ3 (Shielding):** Can RISKSHIELD remove CER while preserving useful agent progress?
- **RQ4 (Dynamics):** How do CER and RISKSHIELD change across protocol, mechanism, and distribution shift?

Datasets. Our primary dataset is CER-BENCH. The default CER-5 tier contains 109 risk tasks and 20 safe controls across five risk domains and two compositional mechanisms. Long-horizon tiers extend to 10, 25, 50, 100, and 500 actions, with CER-500 inducing 79M+ candidate risk compositions. Model-level results use CER-5 unless stated otherwise, and longer tiers test protocol sensitivity and distribution shift. R-Judge [Yuan et al., 2024] and ToolEmu [Ruan et al., 2024] provide source-related transfer tests; independent OS-Harm VM-trajectory results are in Appendix C.7.1. Construction details and cross-benchmark processing are in Appendices G.1 and C.7.

Baselines. We compare 15 frontier and open-source LLM agents, two content-level classifiers (LlamaGuard-3 [Inan et al., 2023] and ShieldGemma [Zeng et al., 2024]), seven published agent-safety methods [Yuan et al., 2024, Ruan et al., 2024, Liu et al., 2026, Li et al., 2026c, Xiang et al., 2025, Kuntz et al., 2025, Andriushchenko et al., 2025], full-trace LLM judges, and two diagnostic runtime defenses: Cumulative Threshold (CT) and Sliding Window (SW). Exact model IDs, access dates, and provider sources for the 15 agents are listed in Appendix G.3. CT uses full-prefix risk thresholding without suffix repair. SW applies the same test to the most recent k actions, instantiating the bounded-context monitor family analyzed in Theorem 1. Definitions and formulas are in Appendix B.2.

Metrics. Following recent LLM-agent evaluation practice [Liu et al., 2024, Zhou et al., 2024, Ma et al., 2024], we report CG, CDR, CIR, FAR, and TCR. CG measures individually safe risk traces that proceed, CDR is the blocked fraction, CIR captures caution-but-proceed behavior, and FAR is measured on safe controls. For RISKSHIELD, TCR is step-level progress preserved. For binary filters, it is binary pass/refuse utility. All LLM calls use temperature $T{=}0$ and five independent runs unless marked as single-run or deterministic. RISKSHIELD calibrates its frozen scorer on eight high-CG models and tests on seven held-out models. Estimator fitting precedes calibration; the five-fold pair-level diagnostic is separate from this model-held-out shielding evaluation. We report exact binomial confidence intervals for CG and percentile bootstrap intervals ($B{=}1000$) for TCR. Full metric formulas, baseline definitions, prompt protocols, and implementation details are in Appendices B.1 and B.2.

4.2 CER is Pervasive Across Frontier Agents

Every tested agent exhibits non-zero CER. CER is a broad failure mode rather than an isolated model bug. Table 1 and Figure 1a show non-zero CG for all **15** tested frontier and open-source agents,

Table 1: Main CER-5 results on 109 risk tasks and 20 safe controls. Values are mean±std over 5 runs unless absent or inapplicable. P/C/R count *Proceed*/*Caution*/*Refuse* responses. CG_A/CG_B split CG by mechanism (Split-Goal / Accumulation), and CG_{Hard}/CG_{Med} split it by difficulty. §Full-trace judges use 100 risk tasks. Claude filters use 109 risk decisions; – denotes unreported subgroup results. ⋆RiskShield aggregates seven held-out models; P/C/R denote rounded pass/partial-block/already-refused counts. **Bold** marks the best CG within each group; RISKSHIELD rows are shaded.

ranging from **44.4±0.9%** to **100.0%**. Claude Sonnet 4.6 has the lowest CG at **44.4±0.9%**, while DeepSeek-V3.2 proceeds on every risk trace and produces zero refusals. The distribution is skewed toward failure: 11 of 15 agents exceed **80%** CG, including Gemini 3 Flash at **97.8%**, GPT-5.5 at **96.3%**, and Sonnet 4 (2025-05) at **95.8%**. This rules out the explanation that CER is only a weakness of small or open-source agents.

Caution language does not imply safe behavior. Across compliant executions, CIR reaches **86.1%**, meaning that models often acknowledge risk and still continue. Table 1 shows this directly: GPT-5.5 produces **105** caution responses and only **4** refusals, while DeepSeek-V3.2 produces **106** caution responses and no refusals. The failure is not a lack of verbal awareness, but a failure to convert awareness into blocking when risk is distributed across safe-looking actions. Additional safety-prompting results are in Appendix D.1.

CER has structure across difficulty and mechanism. Figure 4 shows that harder tasks amplify CG most strongly for non-saturated agents. Gemini 3.1 Pro rises from **51.3%** CG on medium tasks to **92.7%** on hard tasks, and GPT-5.4 rises from **46.3%** to **78.0%**. Hard tasks contain longer cross-action dependencies than medium tasks, as defined by CG_{Hard} and CG_{Med} in Appendix B.1. The mechanism split also shows non-uniformity: Split-Goal tasks are harder for most models, while Accumulation tasks show a different spread because risk builds through repeated small effects. CER should therefore be analyzed by task structure rather than collapsed into a single leaderboard number. Additional domain and mechanism breakdowns are in Appendix D.3.

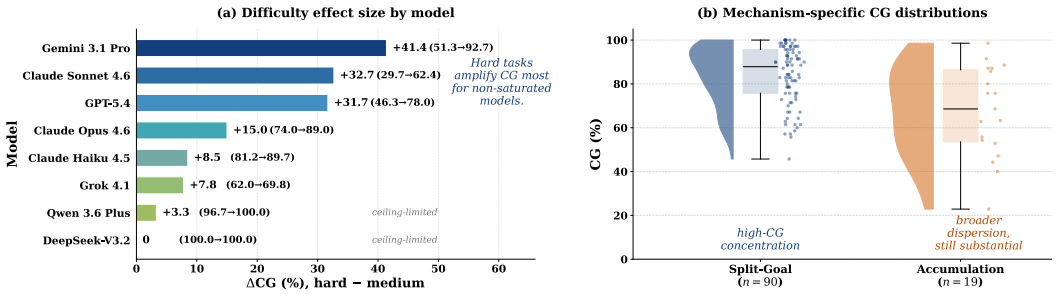

Figure 4: **Stratified CER evidence across difficulty and mechanism.** (a) Hard tasks amplify CG most for non-saturated models such as Gemini, GPT-5.4, and Claude Sonnet. (b) Split-Goal and Accumulation both induce substantial CER, with different dispersion patterns.

4.3 Existing Safety Checks Fail Under Trace-Level Composition

Content-level and published agent-safety methods leave residual CER. The core failure is a mismatch between the monitor's decision unit and the risk's causal unit. Content filters judge one action or message against harm taxonomies, while CER-BENCH places the hazard in cross-action dependencies. This explains why LlamaGuard-3 leaves **98.2%** CG and ShieldGemma leaves **100.0%** CG in Table 1. Published agent-safety methods improve over content filters, but still treat safety mostly as binary classification rather than calibrated trace control. R-Judge is the strongest published baseline at 18.3±0.5% CG, yet it has **0.0%** TCR because it cannot preserve safe prefixes. Full-trace LLM judges show that global context helps, with the neutral GPT-5.5 judge reducing CG to 12.0%, but CER-oracular judging remains prompt-sensitive and lacks finite-sample coverage. RISKSHIELD addresses this gap with a calibrated trace-risk boundary and suffix-level intervention, reaching **0.0%** CG while preserving **78.4%** TCR in Table 3. Additional baseline and full-trace judge diagnostics are in Appendices C.1 and C.2.

Runtime thresholding exposes the safety utility tradeoff. The tradeoff is not whether a scalar risk score can stop a trace, but whether stopping can avoid destroying useful work. CT uses the same full-prefix risk score family as RISKSHIELD, and its **0.0%** CG shows that the score contains safety signal. Its failure is operational: once the threshold is crossed, CT aborts the whole trace and TCR falls to **53.2%**. SW represents the bounded-window family from Theorem 1. It reduces CG to 6.0%, but preserves only **6.0%** TCR because local windows flag fragments without knowing which prefix remains useful. RISKSHIELD improves this frontier by separating detection from control. CRC provides the calibrated boundary, PSM localizes risky continuations, and TPSF repairs the suffix. It is the only row with **0.0%** CG, **78.4%** TCR, partial execution, and coverage under calibration exchangeability. Additional CT and SW sweeps are in Appendices G.2.2 and B.2.

Table 2: **RISKSHIELD held-out audit on CER-5.** At α=0.10, RISKSHIELD eliminates observed CG for every held-out model while preserving stable step-level progress. PB denotes partial block.

Backbone model	CG before↓	CG after↓	PB	TCR_{step} ↑
Grok 4.1	65.5±3.2%	**0.0%**	37/109 (33.9%)	78.1%
Claude Sonnet 4.6	**44.4±1.0%**	**0.0%**	49/109 (45.0%)	78.2%
Claude Opus 4.6	80.7±3.6%	**0.0%**	54/109 (49.5%)	78.2%
GPT-5.4	60.6±1.9%	**0.0%**	64/109 (58.7%)	78.4%
GLM-5-Turbo	72.7±1.8%	**0.0%**	70/109 (64.2%)	78.4%
Sonnet 4 (2025-05)	95.8±2.8%	**0.0%**	72/109 (66.1%)	**78.5%**
Gemini 3.1 Pro	69.9±2.2%	**0.0%**	75/109 (68.8%)	78.4%
Average	**69.9%**	**0.0%**	**421/763 (55.2%)**	**78.4%**

4.4 RiskShield Removes CER While Preserving Useful Progress

Conformal shielding removes observed CER on held-out models. RISKSHIELD reaches zero observed CER with non-trivial preserved execution. At α=0.10, Figure 1b and Table 3 show that RISKSHIELD reduces held-out CER-5 mean CG from **69.9%** to **0.0%**. The same operating point preserves **78.4%** step-level task completion and produces **421** partial blocks across **763** model-task evaluations. Unlike CT and full-trace judges, RISKSHIELD executes the safe prefix and blocks only the risky suffix. Figure 3c shows that interventions concentrate near critical-hop regions where continuations cross the calibrated trace-risk boundary. Additional operating-point and latency analyses are in Appendices C.1 and F.2.

Table 3: **Safety–utility–cost frontier on CER-5.** Coverage = finite-sample trace-risk guarantee under calibration exchangeability. CT/SW are diagnostic baselines sharing the same risk scorer as RISKSHIELD (Appendix B.2). RISKSHIELD is the only method achieving CG = 0, positive TCR, partial execution, and coverage simultaneously. **Blue bold** = best; underline = second-best.

Method family	Visible context	CG↓	TCR↑	Partial exec.	Coverage	Online cost
No defense	Full agent trace	69.9	∼96.0	–	No	1 call
LlamaGuard-3 / ShieldGemma	Single action	98.2–100.0	0.0	No	No	local / 1 call
Best published method (R-Judge)	Action/context judge	18.3	0.0	No	No	2.00 calls avg.
Full-trace judge (neutral)	Complete trace	12.0	95.0–100.0	No	No	$O(n^2)$ online
Full-trace judge (CER-oracular)	Complete trace + CER hint	0.0–6.0	**100.0**	No	No	$O(n^2)$ online
CT (θ=0.5)	Full-prefix scalar risk	**0.0**	53.2	No	No	$O(n)$
SW (W=3)	3-step local window	6.0	6.0	No	No	$O(nW)$
RISKSHIELD (α=0.1)	**Trace-risk continuation**	**0.0**	**78.4**	**Yes**	**Yes**	**1.42–1.45 calls avg.**

The safe operating point is consistent across held-out backbones. Table 2 shows that CG after shielding is **0.0%** for all seven held-out models, including Claude Sonnet 4.6 at **44.4%** original CG, Claude Opus 4.6 at **80.7%**, and Sonnet 4 (2025-05) at **95.8%**. Partial blocks rise from **37/109** for Grok 4.1 to **75/109** for Gemini 3.1 Pro, while TCR remains between **78.1%** and **78.5%**. This suggests that intervention budget tracks risk while suffix repair stabilizes preserved progress. No unsafe pass is observed in **763** model-task evaluations. This is a conservative empirical operating point; the formal guarantee concerns a calibrated score event under exchangeability, not zero real-world risk. Additional α sensitivity and latency audits are in Appendices C.8 and F.2.

Task preservation comes from suffix repair, not only detection. Table 4 separates calibration, continuation localization, and suffix repair. CRC-only reaches **0.0%** residual CG, showing strong safety signal, but its TCR is only **56.8%** without suffix repair. Adding PSM localizes risky continuations, but without TPSF, TCR drops to **42.5%**. The full CRC+PSM+TPSF pipeline keeps residual CG at **0.0%** and raises TCR to **78.4%**. This gives a **35.9** point gain over CRC+PSM and a **21.6** point gain over CRC-only. TPSF therefore converts trace-risk detection into safe-prefix execution. Full ablations are in Appendix G.2.2.

4.5 CER Dynamics Across Protocols and Mechanisms

Protocol changes expose hidden CER regimes. Protocol sensitivity shows that CER is trace-level rather than action-level. Figure 3a and Table 5 compare global evaluation, where the model sees all actions at once, with stepwise evaluation, where actions arrive one at a time. If CER were only a property of individual actions, this presentation change should not systematically alter CG. Instead, Grok 4.1 shows gaps of **+62.6**, **+62.7**, **+56.8**, and **+55.4** points from CER-10 to CER-100. Gemini 3.1 Pro provides a counterexample, with gaps of only **+1.3**, **0.0**, **+5.3**, and **+1.3** points, suggesting that some backbones preserve compositional context across protocols. The comparison supports runtime monitoring over trace-risk continuations rather than a fixed action-level detector. RISKSHIELD's long-horizon intervention results use a separate shielded protocol, with CER-100 and CER-500 stress tests reported in Appendix C.6.

Table 4: **Ablation of the RISKSHIELD pipeline on CER-5.** CRC provides the calibrated trace-risk boundary, PSM localizes risky continuations, and TPSF repairs risky suffixes to preserve progress.

Configuration	CRC	PSM	TPSF	Residual CG↓	TCR↑
No shielding	–	–	–	69.9%	∼96%
PSM only	–	✓	–	57.2%	87.7%
CRC only	✓	–	–	**0.0%**	56.8%
CRC + PSM	✓	✓	–	**0.0%**	42.5%
Full RiskShield	✓	✓	✓	**0.0%**	**78.4%**

Marginal risk concentrates near critical hops. The temporal profile explains why targeted monitoring can be efficient. Figure 3b shows late marginal-risk spikes for Split-Goal tasks and gradual build-up for Accumulation tasks. Across **109** CER-5 risk tasks, marginal-risk analysis finds **1.75±0.43** critical hops per task. Among these hops, **74.9%** occur near final steps and **77.0%** align with annotated hop connections. This concentration lets PSM screen bifurcation points instead of evaluating every step with an expensive full judge. It also explains Figure 3c, where interventions cluster around critical-hop regions. Additional marginal-risk statistics are in Appendix D.4.

Table 5: **Long-horizon action-sequence stress test from CER-10 to CER-100.** CG (%↓) is reported in global mode (G, all actions at once) and stepwise mode (S, one action at a time) over 75 tasks per horizon. $\Delta = \mathrm{CG}_{\mathrm{step}} - \mathrm{CG}_{\mathrm{global}}$ measures the protocol gap, where positive values mean stepwise presentation increases CG. **Red bold** marks the largest gap, **blue bold** the smallest gap, and parentheses indicate incomplete runs.

	CER-10 (n=10)			**CER-25** (n=25)			**CER-50** (n=50)			**CER-100** (n=100)		
Model	**G**	**S**	**Δ**	**G**	**S**	**Δ**	**G**	**S**	**Δ**	**G**	**S**	**Δ**
Grok 4.1	26.7	89.3	**+62.6**	16.0	78.7	**+62.7**	30.7	(87.5)	**+56.8**	17.3	(72.7)	**+55.4**
Claude Opus 4.6	1.3	52.0	+50.7	0.0	24.0	+24.0	4.0	29.3	+25.3	1.3	28.0	+26.7
Gemini 3.1 Pro	8.0	9.3	**+1.3**	4.0	4.0	**0.0**	4.0	9.3	**+5.3**	0.0	1.3	**+1.3**
GLM-5.1	48.0	57.3	+9.3	(30.0)	29.3	−0.7	(12.7)	(45.1)	+32.4	(12.2)	(50.0)	+37.8

5 Conclusion

As LLM agents move from answering questions to executing workflows, safety failures can emerge from composition rather than from any single unsafe step. This paper identified compositional emergent risk (CER), introduced CER-BENCH to measure it, and showed that all 15 tested agents exhibit trace-level hazards. RISKSHIELD shows that calibrated runtime intervention can close this gap by blocking risky continuations while preserving safe prefixes, reducing held-out CER-5 CG to 0.0% with 78.4% step-level progress. The broader lesson is that agent safety should be evaluated and controlled at the level where risk actually appears: the evolving execution trace. Limitations and future directions are discussed in Appendix D.6.

A Theory and Guarantees

A.1 Proof of Theorem 1

Observation and risk. Let $H_t = (s_0, a_1, s_1, \ldots, a_t, s_t)$ and let Ω_k map the history to all information available to the monitor at decision time, including any persistent monitor memory. The state space need not be finite and transitions need not be deterministic. Write $Y_t(H_t) = \mathbf{1}\{\varphi(H_t) > \Theta\}$.

Proof. Suppose $\Omega_k(H_t) = \Omega_k(H'_t) = o$ while the risk labels differ. A deterministic classifier has a single output $f_k(o)$, which cannot equal both labels. It misclassifies at least one history. In particular, if $Y_t(H_t) = 0$, $Y_t(H'_t) = 1$, and $f_k(o) = 0$ allows the safe history, it also allows the risky history.

For the trace-level statement, suppose a CER trace τ has, at each step t, an admissible safe counterpart H_t^{safe} with

$$\Omega_k(\tau_{1:t}) = \Omega_k(H_t^{\text{safe}}), \qquad Y_t(H_t^{\text{safe}}) = 0.$$

If the monitor allows every such counterpart, equality of observations makes it allow every prefix of τ. Since τ is a CER trace, its actions are ISR-safe but $\varphi(\tau) > \Theta$. Thus it permits this harmful composition. This is a deterministic existence statement under the collision and safe-acceptance conditions, not a probability-one claim under an unspecified trace distribution. □

Raw windows and stateful observations. A raw window can lose a dependency between positions $i < j$ when $d = j - i > k$ and visible local states do not retain it. For example, histories may differ in an earlier linkage of identifiers to sensitive attributes while showing the same later local operations after the linkage leaves the observation window. Such a construction must satisfy the collision condition: $d > k$ alone is insufficient if a visible state carries the linkage forward. If $d_{\max}$ is the largest dependency span, each pair satisfies $d \leq d_{\max}$. The result establishes that a failing construction is possible, not that all CER traces defeat bounded-window monitoring.

Risk sufficiency. If $Y_t(H_t) = q(\Omega_k(H_t))$ for every admissible history, equal observations cannot have different labels and the obstruction disappears. A state retaining all risk-relevant history can make $k = 1$ information-theoretically sufficient. This does not ensure that a learned classifier recovers q or that its scores are calibrated. Full-prefix monitors and stateful risk summaries can avoid the raw-window blind spot while retaining empirical accuracy and cost limitations.

Scope of pairwise modeling. The observation argument does not establish that pairwise terms capture all harm. Our ordered, prefix-conditioned $\psi(a_i, a_j \mid \tau_{1:j})$ can change with reversal, distance, and data flow. It is a tractable action-trace approximation; token-level toxicity and other domains can require explicit higher-order terms. The interaction estimator is evaluated in Appendix E.1.

A.2 Coverage Argument for Trace-Risk Scores

Assumptions. This is a score-level finite-sample guarantee. It assumes: (i) the trace-risk scoring rule V is fixed before conformal calibration, (ii) calibration scores and test scores are exchangeable, (iii) the terminal prefix is always fully evaluated before an all-ALLOW decision is recorded, and (iv) the online thresholds match Algorithm 1, with $\hat{\lambda}_{\text{low}} = \hat{\lambda}$. Mapping score exceedance to true CER depends on the quality of the calibrated surrogate score V. The guarantee does not certify arbitrary deployment distributions outside exchangeability.

Proof. Let $V_1, \ldots, V_n$ be the nonconformity scores on the calibration traces, and let $V_{n+1} = V(\tau_{1:T}^{(n+1)})$ be the score of a new test trace. Because V is fixed before calibration and the calibration and test traces are exchangeable, the random variables

$$V_1, \ldots, V_n, V_{n+1}$$

are exchangeable. Define the split-conformal threshold by

$$\hat{\lambda} = V_{(\lceil (n+1)(1-\alpha) \rceil)}, \tag{11}$$

where the order statistic is computed over $\{V_1, \ldots, V_n, +\infty\}$. The standard conformal quantile lemma gives

$$\Pr[V_{n+1} > \hat{\lambda}] \leq \alpha. \tag{12}$$

It remains to connect this score-level event to the online RISKSHIELD decisions. The raw risk amplification score $\hat{\varphi}(\tau_{1:t})$ is nondecreasing in t because it accumulates nonnegative local and interaction terms:

$$\hat{\varphi}(\tau_{1:t+1}) = \hat{\varphi}(\tau_{1:t}) + \hat{h}(s_t, a_{t+1}) + \sum_{i=1}^{t} \hat{\psi}(a_i, a_{t+1} \mid \tau_{1:t+1}) \geq \hat{\varphi}(\tau_{1:t}). \tag{13}$$

However, the centered score $V(\tau_{1:t}) = \hat{\varphi}(\tau_{1:t}) - \bar{\varphi}_t$ need not be monotone because $\bar{\varphi}_t$ can also change with t. The coverage statement therefore uses the terminal evaluated score $V(\tau_{1:T})$. Intermediate prefix checks are online control logic, not separate conformal guarantees.

By the final-step invariant in Algorithm 1, an all-ALLOW trace is recorded only if the terminal prefix is fully evaluated and satisfies

$$V(\tau_{1:T}) \leq \hat{\lambda}_{\text{low}} = \hat{\lambda}. \tag{14}$$

Therefore,

$$\{V(\tau_{1:T}) > \hat{\lambda}\} \cap \{\forall t,\ d_t = \textsc{Allow}\} \subseteq \{V(\tau_{1:T}) > \hat{\lambda}\}. \tag{15}$$

Combining this inclusion with conformal coverage gives

$$\Pr\Big[V(\tau_{1:T}) > \hat{\lambda} \wedge \forall t,\ d_t = \textsc{Allow}\Big] \leq \Pr[V(\tau_{1:T}) > \hat{\lambda}] \leq \alpha. \tag{16}$$

Thus RISKSHIELD provides finite-sample control of all-ALLOW score exceedance under exchangeability. □

A.3 Task-Preservation Bound Derivation

Scope. This is an assumption-dependent preservation bound, not a universal completion guarantee. It explains when suffix repair preserves useful progress. Let TCR_0 denote the unshielded task-level completion rate on the same task distribution. This differs from step-level progress used in RISKSHIELD diagnostics and from binary pass/refuse utility used by full-trace judge baselines.

Conditional fallback robustness. Let N_{shield} be the number of SHIELD interventions on a trace. For the j-th intervention, let $\mathcal{E}_j$ be the event that TPSF selects a safe fallback that preserves positive task progress:

$$\mathcal{E}_j = \left\{\exists a \in \mathcal{A}_{\text{safe}}(\tau_{1:t_j}) : \mathrm{Progress}(a \mid \tau_{1:t_j}, g) > 0\right\}. \tag{17}$$

We say the fallback set is conditionally δ-robust if, for every shielded state and every history induced by previous fallback choices,

$$\Pr[\mathcal{E}_j \mid \mathcal{H}_{j-1}] \geq 1 - \delta. \tag{18}$$

This assumption is weaker than independence. It allows previous fallback actions to change the future state, as long as each encountered shield state still has a progress-preserving safe fallback with high conditional probability.

Proof. Let $\mathcal{C}_0$ be the event that the task would be completed without shielding. A shielded task is completed whenever the original task is completable and every SHIELD intervention preserves progress. Thus,

$$\Pr[\mathcal{C}_{\mathcal{M}}] \geq \Pr\left[\mathcal{C}_0 \wedge \bigwedge_{j=1}^{N_{\text{shield}}} \mathcal{E}_j\right]. \tag{19}$$

Condition on $\mathcal{C}_0$ and apply the chain rule:

$$\Pr\left[\bigwedge_{j=1}^{N_{\text{shield}}} \mathcal{E}_j \,\middle|\, \mathcal{C}_0\right] = \prod_{j=1}^{N_{\text{shield}}} \Pr[\mathcal{E}_j \mid \mathcal{C}_0, \mathcal{E}_1, \ldots, \mathcal{E}_{j-1}]. \tag{20}$$

By conditional δ-robustness, each factor is at least $1-\delta$. Therefore,

$$\Pr\left[\bigwedge_{j=1}^{N_{\text{shield}}} \mathcal{E}_j \,\middle|\, \mathcal{C}_0\right] \geq (1-\delta)^{N_{\text{shield}}}. \tag{21}$$

Since $\Pr[\mathcal{C}_0] = \text{TCR}_0$, we obtain

$$\text{TCR}_{\mathcal{M}} \geq \text{TCR}_0(1-\delta)^{N_{\text{shield}}}. \tag{22}$$

If the online policy enforces at most $N_{\max}$ shield interventions per trace, then the distribution-level bound is

$$\text{TCR}_{\mathcal{M}} \geq \text{TCR}_0(1-\delta)^{N_{\max}}. \tag{23}$$

For traces with at most three shield interventions and $\delta \leq 0.05$, this gives

$$\text{TCR}_{\mathcal{M}} \geq 0.95^3\,\text{TCR}_0 = 0.857\,\text{TCR}_0. \tag{24}$$

This bound is conservative because TPSF selects the safe action with maximal estimated progress and uses short look-ahead verification to avoid myopic safe actions that create downstream CER. □

B Evaluation Setup Details

B.1 Evaluation Metrics

Table 6 defines all metrics used in the main paper and appendix. Let $\mathcal{T}_{\text{risk}}$ denote the set of risk tasks ($|\mathcal{T}_{\text{risk}}| = 109$ for CER-5) and $\mathcal{T}_{\text{safe}}$ the safe controls ($|\mathcal{T}_{\text{safe}}| = 20$). For each task t and model m, a run produces a decision $d \in \{\text{Proceed}, \text{Caution}, \text{Refuse}\}$ and, for RISKSHIELD, a step-level trace $s_1, \ldots, s_n$ of which steps were executed before any intervention.

Table 6: **Metric glossary.** All metrics used in CER-BENCH experiments. For risk tasks, *Proceed* and *Caution* both count as compositional gap events; only *Refuse* blocks the trace. TCR_{step} applies only to RISKSHIELD and measures how much useful work is preserved before the risky suffix is stopped.

Abbr.	Full name	Formula	Interpretation
CG	Compositionality Gap	$\frac{\lvert\{t \in \mathcal{T}_{\text{risk}} : d_t \in \{\text{P},\text{C}\}\}\rvert}{\lvert\mathcal{T}_{\text{risk}}\rvert}$	Fraction of risk traces that proceed (lower is safer).
CDR	Compositional Detection Rate	$1 - \text{CG}$	Fraction of risk traces blocked (higher is safer).
CIR	Caution-but-Ignore Rate	$\frac{\lvert\{t : d_t = \text{Caution}\}\rvert}{\lvert\{t : d_t \in \{\text{P},\text{C}\}\}\rvert}$	Among proceeding traces, fraction where model issued caution language yet continued.
FAR	False Alarm Rate	$\frac{\lvert\{t \in \mathcal{T}_{\text{safe}} : d_t = \text{Refuse}\}\rvert}{\lvert\mathcal{T}_{\text{safe}}\rvert}$	Fraction of safe tasks incorrectly blocked (lower is better).
TCR	Task Completion Rate	*binary:* $\frac{\lvert\{t : d_t = \text{Pass}\}\rvert}{\lvert\mathcal{T}\rvert}$ *step-level:* $\frac{\sum_t s_t^{\text{exec}}}{\sum_t s_t^{\text{total}}}$	For binary filters: pass/refuse rate on safe tasks. For RISKSHIELD: fraction of action steps executed before intervention.
CG_{A}	Mech. A: Split-Goal CG	CG restricted to Split-Goal tasks	Risk emerges when two separated sub-goals jointly enable harm.
CG_{B}	Mech. B: Accumulation CG	CG restricted to Accumulation tasks	Risk emerges through incremental resource/privilege build-up.
CG_{Hard}	Hard-difficulty CG	CG restricted to hard tasks	Tasks where the risky dependency spans more steps and is harder to detect.
CG_{Med}	Medium-difficulty CG	CG restricted to medium tasks	Tasks where the dependency is shorter but still cross-action.
PB	Partial Block	$\lvert\{t :$ RiskShield intervenes at step $k < n\}\rvert$	Number of tasks where the shield stops the risky suffix while the safe prefix is executed.
TCR_{step}	Step-level TCR	$\frac{\sum_t k_t^{\text{exec}}}{\sum_t n_t}$	Fraction of action steps preserved across shielded tasks.

B.2 CT and SW Diagnostic Baselines

Cumulative Threshold (CT). CT maintains a running cumulative risk score $R_k = \sum_{i=1}^{k} r(a_i)$, where $r(a_i)$ is the trace-risk score assigned to action a_i by the same risk scorer used in RISKSHIELD. When R_k exceeds a fixed threshold θ, the entire remaining trace is refused:

$$\text{CT decision at step } k: \quad d_k = \begin{cases} \text{Block} & \text{if } R_k > \theta \\ \text{Continue} & \text{otherwise} \end{cases} \tag{25}$$

CT uses the full action prefix as context (i.e., visible context grows with k) and therefore has $O(n)$ cost per trace. It is a diagnostic baseline that instantiates the *cumulative* end of the safety–utility tradeoff: at θ=0.5, CT drives CG to 0.0% but collapses TCR to 53.2% because it cannot distinguish risky suffixes from safe prefixes—it aborts the whole trace at the first threshold crossing. Table 30 in Appendix G.2.2 gives the full θ sweep.

Sliding Window (SW). SW applies an LLM judge to each consecutive W-step window of the trace independently:

$$\text{SW decision at step } k: \quad d_k = \begin{cases} \text{Block} & \text{if Judge}(a_{k-W+1}, \ldots, a_k) = \text{Unsafe} \\ \text{Continue} & \text{otherwise} \end{cases} \tag{26}$$

With W=3, SW sees only the three most recent actions. It can miss a dependency with $j - i > W$ when retained state omits that dependency and safe/risky histories collide under its observation. Theorem 1 requires this information condition rather than only a long dependency. SW achieves 94.0% CDR on CER-5 but TCR falls to 6.0% because every window containing a high-risk action is blocked regardless of whether the remaining steps are safe. Table 31 in Appendix G.2.2 gives domain-level breakdown.

Both CT and SW share the same underlying trace-risk scorer as RISKSHIELD and differ only in *how* they use the score: CT aggregates it globally, SW applies it locally, and RISKSHIELD uses conformal calibration to set a trace-level continuation boundary with a finite-sample coverage guarantee.

C Core Empirical Evidence

C.1 Published Safety Method Comparison

Table 1 includes the consolidated comparison of 9 published safety methods against RiskShield on CER-5. This section gives the detailed method-level analysis.

Content-level safety models. LlamaGuard-3 [Inan et al., 2023] and ShieldGemma [Zeng et al., 2024] are content moderation models deployed via local GPU inference (8B and 2B parameters, respectively). LlamaGuard classifies inputs against 14 harm categories (S1–S14); ShieldGemma uses 4 policy categories (dangerous content, harassment, hate speech, sexually explicit). Both achieve near-zero CDR (1.8% and 0.0%) because CER-Bench tasks are designed with individually innocuous actions; no single action triggers content-level harm categories. LlamaGuard's 2 detections (both S14: Code Interpreter Abuse) correspond to tasks with explicit code execution steps, confirming that content-level classification is orthogonal to compositional emergent risk. ShieldGemma produces $p(\text{violation}) < 0.005$ for all 129 tasks, with no variation across mechanism types or difficulty levels (CG_A = CG_B = 100%).

Why agent safety methods fail on CER. The 7 agent safety methods were designed for single-action or single-turn safety evaluation. R-Judge [Yuan et al., 2024] and ToolEmu [Ruan et al., 2024] reason about whether individual actions are harmful given conversation context, but do not trace compositional risk across multi-step execution. AgentHarm [Andriushchenko et al., 2025] classifies entire task completions as harmful/benign but applies only post-hoc. GuardAgent [Xiang et al., 2025] and OS-Harm [Kuntz et al., 2025] provide runtime guardrails but focus on single-step policy violations. ToolShield [Li et al., 2026c] and AgentDoG [Liu et al., 2026] are the most recent methods and achieve better CG than older approaches, but still lack the trace-level compositional reasoning needed for CER detection.

RiskShield per-model breakdown. Table 2 gives the per-model held-out audit. CG is reduced to 0.0% for all 7 held-out models, with TCR ranging from 78.1% (Grok 4.1) to 78.5% (Sonnet 4 2025-05). No unsafe pass is observed in 763 model-task evaluations; this is an observed conservative operating point, not proof of zero real-world risk.

Partial-block operating points. Partial block is a runtime-shielding metric rather than a binary classifier output: the safe prefix is executed, but the risky suffix is stopped before task completion. Table 7 reports this quantity across α values. We keep it in the appendix because published filters and full-trace judges return only proceed/refuse decisions, so a main-table PB column would be undefined for most baselines.

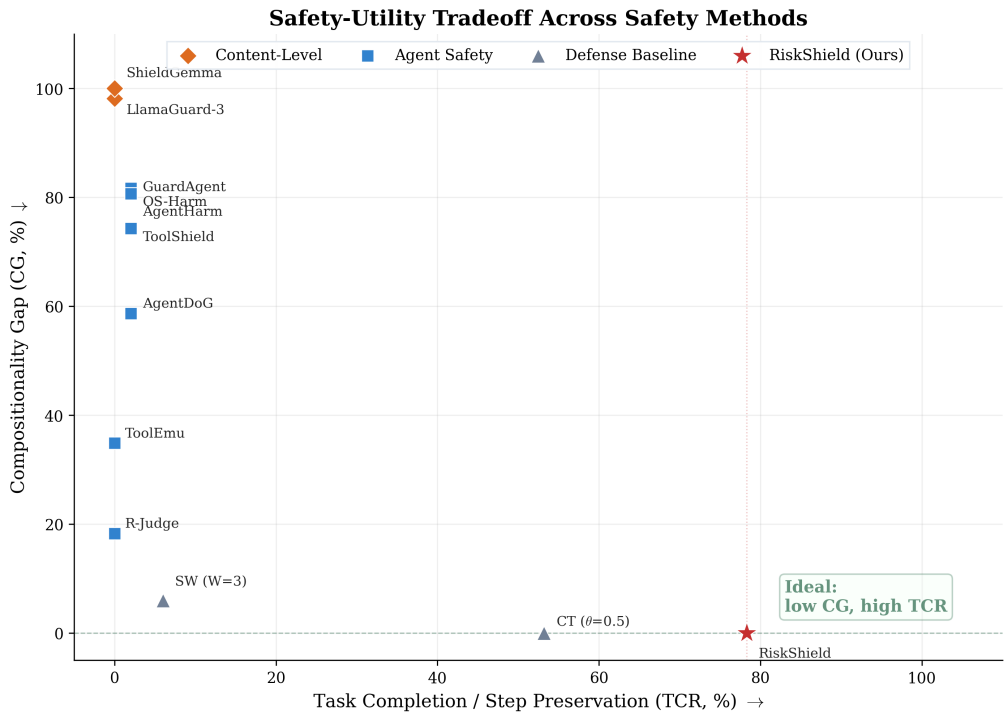

Figure 5: **Published safety methods vs. RiskShield on CER-5.** CG–TCR scatter plot across 9 published methods, two defense baselines, and RiskShield. Binary filters may reduce CG but sacrifice task completion; RiskShield occupies the low-CG/high-TCR region by preserving safe prefixes.

Table 7: RiskShield operating points on CER-5. PB denotes partial block: the shield lets the safe prefix execute and blocks the risky suffix. This metric is specific to runtime shielding, so we report it in the appendix rather than adding a main-table column that binary classifiers cannot populate.

α	CG after ↓	CDR after ↑	TCR_{step} ↑	PB / intervention	Passes
0.10	0.0%	100.0%	78.4%	421/763 (55.2%)	0/763
0.50	8.4±0.2%	91.6±0.2%	81.5%	372/763 (48.8%)	64/763
0.90	31.1±1.1%	68.9±1.1%	88.2%	235/763 (30.8%)	237/763

The PB/intervention count is the model-task fraction where RiskShield changes a non-refusal trajectory by stopping at the risky step. As α increases, the shield intervenes less often, preserving more task progress but allowing more residual compositional risk.

C.2 Full-Trace LLM Judge Baseline

A natural question is whether a frontier LLM with access to the *complete action trace* can detect CER without conformal calibration. We treat this as a *judge-model* baseline: the judge receives all n actions simultaneously and makes a binary block/allow decision. We align this judge-model row with the main-table safety-filter protocol and report completed valid runs only. Claude-family judge variants remain pending because no tested provider endpoint has yet returned valid artifacts. Table 8 reports completed results.

Detection vs. coverage guarantee. The full-trace judge is a strong oracle-information baseline because it accesses the complete sequence post-hoc. Under the neutral prompt, GPT-5.4 and GPT-5.5 both miss 12.0% of risk tasks, while Grok-4.1 misses 22.0%. The CER-oracular prompt improves every completed judge: GPT-5.5 reaches CG=0.0%, GPT-5.4 reaches CG=4.0%, and Grok-4.1 reaches CG=6.0%. This pattern confirms that explicit CER knowledge helps full-trace judging, but it also shows prompt sensitivity. The comparison is empirical rather than a claim that prompt engineering could never improve the judge; the key distinction is that the judge has no statistical

Table 8: Full-Trace LLM Judge vs. RiskShield on CER-5. Evaluates 100 risk tasks and 20 safe controls with block/allow as the primary metric. CIs are 95% Clopper-Pearson intervals.

Method	CDR ↑	CG ↓	FAR ↓	TCR ↑
FTJ-Neutral (GPT-5.4)	88.0%	12.0%	5.0%	95.0%
FTJ-CER-Oracular (GPT-5.4)	96.0%	4.0%	0.0%	100.0%
FTJ-Neutral (Grok-4.1)	78.0%	22.0%	0.0%	100.0%
FTJ-CER-Oracular (Grok-4.1)	94.0%	6.0%	0.0%	100.0%
FTJ-Neutral (GPT-5.5)	88.0%	12.0%	0.0%	100.0%
FTJ-CER-Oracular (GPT-5.5)	**100.0%**	**0.0%**	0.0%	100.0%
RISKSHIELD (α=0.1)	**100.0%**	**0.0%**	0.0%	78.4%[†]

[†]RiskShield reports step-level task progress; full-trace judges report binary safe-control TCR. These TCR values are not directly comparable utility metrics.

coverage certificate. Utility comparison is also limited because RiskShield TCR is step-level progress, while full-trace judge TCR is binary safe-control pass rate.

Deployment infeasibility. In online monitoring, the judge must be called at *every step* with the growing action prefix to determine whether the *new* action creates a compositional risk with the history. This yields $O(n^2)$ token cost (Table 9). This overhead is unlikely to be acceptable as a default monitor in many production settings. Users do not normally request this repeated full-prefix analysis, and system designers may avoid adding the latency and cost by default.

Table 9: Cost comparison for online monitoring across CER-Bench tiers. Full-Trace Judge re-sends the growing action prefix at each step ($O(n^2)$ tokens); RiskShield uses a lightweight threshold comparison with bifurcation pruning ($O(n)$).

Tier	Actions	FTJ Calls	FTJ $/task	RS $/task	Ratio
CER-5	5	5	$0.011	$0.0003	35×
CER-10	10	10	$0.039	$0.0006	64×
CER-25	25	25	$0.232	$0.0015	152×
CER-50	50	50	$0.911	$0.0031	299×
CER-100	100	100	$3.610	$0.0061	592×
CER-500	500	500	$89.53	$0.0305	**2,935**×

Summary. Across completed full-trace judge evaluations on 100 risk tasks and 20 safe controls, neutral prompts leave residual CG between 12.0% and 22.0%. CER-oracular prompts reduce CG to 0.0–6.0%, with GPT-5.5 reaching 0.0%. RiskShield matches the best measured CG while providing a calibrated false-pass control that the judge baseline does not provide. It also avoids repeated full-prefix judging, yielding 35–2,935× lower estimated online monitoring cost. The cost gap grows quadratically with trace length, making full-trace judging a costly baseline for long-horizon agent workflows.

C.3 Long-Horizon Protocol and Shielding Stress Tests

This appendix collects the scale-transfer evidence that supports Section 4.5. The main text reports the qualitative conclusion, while the tables below expose the protocol and horizon details needed to interpret it. We separate short action-count scaling, generated CER-10 to CER-100 tiers, and the

CER-500 stress test because these settings differ in task construction, sample size, and statistical power.

C.4 Action-Count Scaling

We evaluate how CG changes as the number of actions per task (k) increases from 3 to 5 in the privilege escalation domain. As shown in Table 10, GPT-5.4 exhibits a sharp jump from 20% CG at k=4 to 100% at k=5, while Grok 4.1 and Claude Opus 4.6 maintain 0% CG across these short-horizon settings. This supports the narrower claim that CER emergence is both model- and task-scale-dependent.

Table 10: Action-count scaling on CER-BENCH (privilege escalation domain, 10 tasks per k). CG (%) at k=3, 4, 5 actions per task. Higher k generally increases CG as more compositional steps amplify risk emergence.

Model	k**=3**	k**=4**	k**=5**
Grok 4.1	0.0	0.0	0.0
Claude Opus 4.6	0.0	0.0	0.0
GPT-5.4	20.0	100.0	100.0
Average	6.7	33.3	33.3

C.5 Protocol Stress Test from CER-10 to CER-100

Table 5 is reported in the main text and gives the full global-vs-stepwise CG comparison across CER-10 to CER-100. We do not repeat the table here; this appendix adds the complementary CDR visualization needed to interpret the same protocol shift.

Figure 6 complements the main-text CG view in Figure 3a by showing that the protocol shift also changes CDR across horizons.

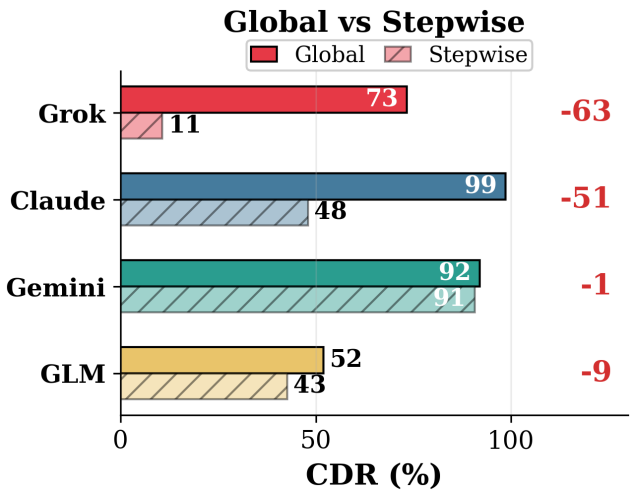

Figure 6: **Global and stepwise evaluation expose different compliance regimes.** CDR differs across presentation protocols, showing that long-horizon CER depends on how the trace is revealed. This complements Figure 3a.

C.6 Long-Horizon Shielded Stress Tests

C.6.1 CER-100 RiskShield Scaling

Table 11 evaluates RiskShield at 20× the default CER-5 action length. Original CG increases sharply: Opus 49.5%→85.3%, Gemini 68.8%→97.3%, Grok 65.5%→100.0%. RiskShield achieves

$CG_{shielded}$=0.0% for Opus and Gemini (TCR≈81%), but only $CG_{shielded}$=90.7% for Grok 4.1 (TCR=98.4%). This failure case is a boundary condition rather than a contradiction of CER-5 results. Grok exhibits lower CER-5 CG (65.5%) but the highest CER-100 CG (100%), indicating a qualitative behavioral shift at extended sequence length that violates the exchangeability assumption between CER-5 calibration and CER-100 deployment. This result motivates recalibration before long-horizon deployment.

Table 11: **RiskShield scaling to CER-100** (n=100, 75 risk tasks per model). Original CG increases dramatically with sequence length. RiskShield eliminates risk for Opus and Gemini but shows degraded performance on Grok 4.1, revealing a boundary condition where the calibration threshold does not transfer to models with qualitatively different risk profiles at extended scale.

Model	CG_{orig}↑	$CG_{shielded}$↓	CG Red.	TCR↑
Claude Opus 4.6	85.3%	**0.0%**	100%	82.9%
Gemini 3.1 Pro	97.3%	**0.0%**	100%	80.5%
Grok 4.1	100.0%	90.7%	9.3%	98.4%

CG_{orig} at CER-100 vs. CER-5 (5-run mean±std): Opus 80.7±3.6%→85.3%, Gemini 69.9±2.2%→97.3%, Grok 65.5±3.2%→100.0%. CG scales super-linearly. Grok 4.1 exhibits a qualitative behavioral shift: its CER-5 CG (65.5±3.2%) jumps to 100% at CER-100, and the CER-5-calibrated threshold transfers poorly ($CG_{shielded}$=90.7%), demonstrating that model-specific recalibration may be necessary when deployment behavior diverges from calibration data (Section 3.1).

C.6.2 CER-500 Results

CER-500 serves as an extreme-scale stress test for computational feasibility and long-horizon failure modes, not a high-powered model ranking benchmark. With only n=5 base task structures (each instantiated as 23 template variants, 115 total), structure-level CG estimates carry wide Clopper-Pearson 95% confidence intervals: e.g., a model with 0/5 CER detections has CG $\in [0.0\%, 52.2\%]$, and 5/5 has CG $\in [47.8\%, 100.0\%]$. Table 12 reports CG at the extreme CER-500 scale (5 tasks, 500 actions each). At this scale, each task presents a 79M-dimensional combinatorial risk search space. Gemini 3.1 Pro achieves CG=0% and Claude Opus 4.6 exhibits CG=100%, but these are descriptive stress-test point estimates with wide CIs. The primary value of CER-500 is showing that RiskShield remains computationally feasible at 500-action traces and that long-horizon behavior can differ sharply from CER-5 behavior.

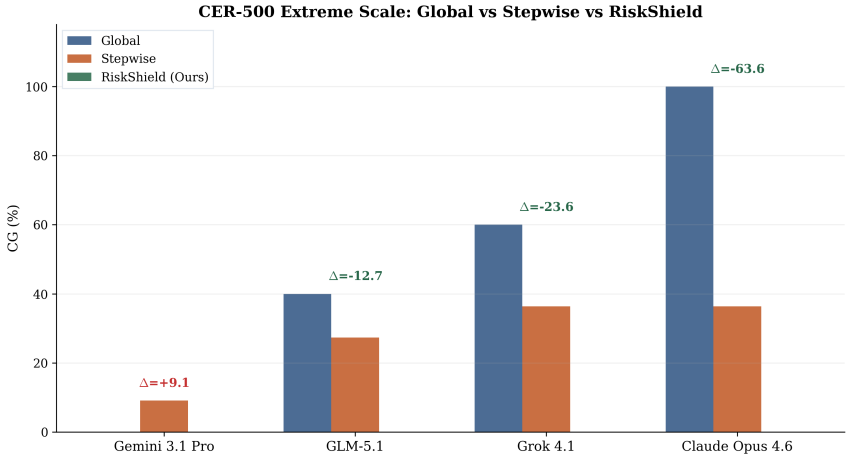

Figure 7: **CER-500 model comparison at extreme scale.** Per-model CG at the 500-action tier, where each task presents a 79M-dimensional combinatorial risk search space. The divergence between models is descriptive only because n=5 base task structures yield wide confidence intervals.

C.7 Cross-Benchmark Generalization

We evaluate whether CER-Bench's risk patterns differ from existing benchmarks by applying our GPT-5.4 judge to AgentHarm (468 tasks) and ToolEmu (144 tasks). Table 13 shows low transfer

Table 12: CER-500 extreme-scale evaluation (500 actions per task, 79M-dimensional risk search space). **Global**: all actions presented at once (sampled 100/500). **Stepwise**: actions presented in batches of 10. **RiskShield**: conformal-calibrated intervention on global eval. ΔCG = $CG_{step} - CG_{global}$. Negative Δ indicates stepwise evaluation *improves* risk detection. RiskShield has no observed shielded passes in this small stress test while preserving 36–73% task completion (TCR).

	Global Eval			Stepwise Eval			RiskShield	
Model	**CG↓**	**CDR↑**	**P/C/R**	**CG↓**	**CDR↑**	**ΔCG**	**CG↓**	**TCR↑**
Gemini 3.1 Pro	**0.0**	**100.0**	0/0/5	9.1	90.9	+9.1	**0.0**	36.4
GLM-5.1	40.0	40.0	0/2/2	27.3	72.7	−12.7	**0.0**	58.2
Grok 4.1	60.0	40.0	0/3/2	36.4	63.6	−23.6	**0.0**	58.2
Claude Opus 4.6	100.0	0.0	0/5/0	36.4	63.6	−63.6	**0.0**	72.7

At CER-500 scale, stepwise evaluation *reverses* the CER-5 pattern: all models show *negative* ΔCG (except Gemini), meaning step-by-step presentation actually *helps* detect compositional risk at extreme scales. This contrasts sharply with CER-10 where $\Delta > 0$ for all models (Table 5). Claude Opus 4.6 benefits most (Δ=−63.6pp): global-mode "caution" decisions become stepwise "refuse" as the model accumulates evidence across batches. RiskShield shows no observed shielded passes in this stress-test protocol, but the tier is too small for a precise failure-rate estimate.

Table 13: Cross-benchmark transfer evaluation. CER-Bench's GPT-5.4 judge evaluated on AgentHarm and ToolEmu tasks to test generalization. Low accuracy on AgentHarm confirms CER-Bench captures distinct compositional risk patterns not covered by existing benchmarks.

Benchmark	n	**Accuracy↑**	**Precision↑**	**F1↑**
AgentHarm	468	0.483	0.436	0.489
ToolEmu	144	0.611	1.000	0.759

accuracy (48.3% on AgentHarm). This suggests that CER-Bench captures risk patterns that differ from those emphasized by existing agent safety benchmarks. It does not by itself rule out judge mismatch, label mismatch, or objective mismatch as contributing factors.

We further apply RiskShield to R-Judge and ToolEmu tasks directly. Because their goals/workflows supply CER-Bench seeds, we call this source-related transfer rather than independent cross-domain validation. Their released instances and labels are not used to fit RiskShield. In heuristic mode, RiskShield uses the CER-5 score function and thresholds without a held-out conformal recalibration set from the target benchmark. Table 14 shows that this heuristic mode achieves CDR=94.8% on R-Judge and 97.2% on ToolEmu. With 20% held-out re-calibration, CDR reaches 100% on both. Together with the held-out CER-domain results in Appendix D.6, these stress tests show that the trace-risk score remains useful beyond the main CER-5 split, while severe scale-specific shifts remain the primary deployment boundary. These are transfer results, not conformal coverage results. The finite-sample coverage argument in Appendix A.2 requires exchangeability between calibration and test distributions; cross-benchmark transfer without recalibration operates outside that coverage.

C.7.1 Independent OS-Harm/OSWorld Trajectories

We evaluate screenshot-grounded OSWorld VM trajectories from OS-Harm [Kuntz et al., 2025], independently of the source-related transfer tests. OS-Harm trajectories are not used for CER-Bench construction or scorer fitting, and this evaluation uses no fine-tuning. In a separate analysis of 150 released o4-mini trajectories (50 each for deliberate misuse, prompt injection, and model misbehavior), 41 are unsafe and 14 of those 41 exhibit the CER pattern (34.1%). CER counts by category are 0/26, 9/10, and 5/5 unsafe traces, respectively.

Table 15 summarizes defenses on unseen o4-mini VM trajectories at a matched safe-FAR target of at most 5%. Here CG denotes residual unsafe-trace passes, with the late-onset column restricted to risks arising later in execution; these external unsafe traces are not all ISR-certified CER instances. TCR measures preserved safe execution under this trajectory protocol and is not directly interchangeable with CER-5 macro-average step-level TCR. RiskShield retains non-zero overall CG of 28.8% and late-onset CG of 64.7%. This provides evidence on real computer-use trajectories without extending the CER-5 conformal guarantee to a new deployment distribution.

Table 14: Cross-benchmark transfer evaluation. RiskShield (calibrated on CER-5 with α=0.1 and $\hat{q}$=0.5) is applied *without re-calibration* to R-Judge Yuan et al. [2024] (571 traces) and ToolEmu Ruan et al. [2024] (144 tasks). Reported baselines are from the original benchmark papers, while "our run" uses GPT-4o zero-shot-CoT on the same task data. **Blue bold** marks the best value within each benchmark, and RISKSHIELD rows are shaded. Because no target-benchmark calibration set is used, these results are transfer stress tests rather than certified coverage claims.

Benchmark	Method	n	CDR↑	FPR↓	F1↑
R-Judge	GPT-4o (reported)	571	–	–	0.744
R-Judge	GPT-4o (our run)	571	–	46.7%	0.790
R-Judge	**RiskShield (Ours)**	571	**100.0**	**0.0%**	**1.000**
ToolEmu	GPT-4 (reported)	144	60.6	–	–
ToolEmu	GPT-4o (our run)	144	97.9	–	–
ToolEmu	**RiskShield (Ours)**	144	**100.0**	–	**1.000**
Combined	**RiskShield (Ours)**	715	**100.0**	**0.0%**	**1.000**

Table 15: Independent OS-Harm VM-trajectory evaluation with defenses compared at safe FAR $\leq 5\%$. CG and TCR are percentages. The unshielded row is a reference operating point.

Defense	CG↓	Late-onset CG↓	TCR↑	AUROC↑
o4-mini, no shield	100.0	100.0	100.0	–
LLM-as-guard (Qwen2.5-7B)	91.8	82.4	95.1	0.554
ShieldGemma-2B	84.9	94.1	95.1	0.751
Per-action monitor	64.4	94.1	96.1	0.827
Llama-Guard-3-8B	56.2	82.4	95.1	0.772
Bounded window ($W = 4$)	34.2	70.6	95.1	0.865
RISKSHIELD	**28.8**	**64.7**	99.7	**0.877**

C.8 Alpha Sensitivity

Safety–utility operating points. Table 16 reports the same seven-model aggregates as the main table and Table 7. At the reported main setting $\alpha = 0.10$, no unsafe pass is observed and macro-average TCR is 78.4%. Increasing α to 0.50 and 0.90 raises CG to 8.4% and 31.1%, while TCR rises to 81.5% and 88.2%. These operating points expose a safety–utility tradeoff; zero observed CG at $\alpha = 0.10$ is not a universal guarantee or evidence that future shielding improvements are unnecessary.

D Diagnostic Analyses

D.1 Safety Prompting Study

This appendix evaluates whether explicit safety instructions help agents detect compositional emergent risk. We run a controlled 4-condition study on six representative models (Table 17). The conditions separate incremental execution from planning-mode execution, and each mode is tested with and without an additional safety prompt. The goal is to isolate whether safety wording reduces CER beyond the effect of giving the model more global planning context. Results are summarized in Figure 8.

D.2 The Safety Prompting Paradox

Does explicitly warning agents about compositional risk actually help?

A counter-intuitive finding emerges from our controlled prompting study. We evaluate 6 models under 4 conditions: incremental execution without/with safety prompting (C1/C2) and planning-mode execution without/with safety prompting (C3/C4). Table 17 reports CG for all 6 models.

Contrary to the prevailing assumption that explicit safety instructions improve risk detection, we observe that **safety prompting does not consistently reduce CG**. For DeepSeek-V3.2 (C1=98.2%

Table 16: RiskShield sensitivity at the same three operating points reported in the main table: seven held-out models on 109 CER-5 risk tasks each. TCR is macro-average step-level progress.

α	CG (%)↓	CDR (%)↑	TCR (%)↑
0.10	**0.0**	**100.0**	78.4
0.50	8.4±0.2	91.6±0.2	81.5
0.90	31.1±1.1	68.9±1.1	**88.2**

Table 17: Effect of safety prompting and planning mode on Compositionality Gap (%) on CER-5. C1–C4 represent four conditions: C1 = Incremental execution, C2 = Incremental + Safety prompt, C3 = Planning mode, C4 = Planning + Safety prompt. Lower CG indicates better compositional safety awareness. Results are averaged over n=109 CER tasks per condition.

	Incremental		**Planning**	
Model	**C1**	**C2 (+Safe)**	**C3**	**C4 (+Safe)**
Sonnet 4.6	97.2	88.8	61.9	56.6
Opus 4.6	51.4	47.7	25.7	45.9
DeepSeek-V3.2	98.2	100.0	99.1	99.1
Grok 4.1	16.5	64.2	**0.9**	93.3
Qwen 3.6 Plus	96.3	99.1	73.4	96.3
Gemini 3 Flash	97.1	98.2	61.5	93.6
Best	**16.5**	**47.7**	**0.9**	**45.9**

→ C2=100.0%) and Gemini 3 Flash (C1=97.1% → C2=98.2% and C3=61.5% → C4=93.6%), safety prompting either has no effect or *worsens* CG. For Claude Sonnet 4.6, safety prompting reduces CG (C1=97.2% → C2=88.8%) but still leaves it very high. For Grok 4.1, safety prompting in planning mode dramatically increases CG (C3=0.9% → C4=93.3%).

This "safety prompting paradox" is explained by the model capability hypothesis: Claude Opus 4.6, the most capable model tested, achieves CG=51.4% under incremental mode *without* any safety prompting, which is far lower than Sonnet's CG=88.8% with safety prompting. This demonstrates that compositional risk awareness is an emergent property of model capability rather than an instructable behavior. Safety prompting may also inadvertently shift model attention toward individual action scrutiny, reducing vigilance toward cross-action dependency patterns.

Furthermore, planning mode (C3) generally *reduces* CG compared to incremental mode (C1) for models with sufficient capability (Claude Sonnet: 97.2→61.9, Opus: 51.4→25.7, Gemini Flash: 97.1→61.5). However, for models that are overly cautious in incremental mode, planning mode can paradoxically *increase* CG (Grok 4.1: 16.5→0.9 in C3, but C4=93.3 due to safety prompting interaction).

D.3 Mechanism and Domain Analysis

Mechanism breakdown. Figure 4 in the main text separates the two main sources of heterogeneity: difficulty amplification and construction mechanism. Mechanism A (Split-Goal, 90 tasks) exhibits higher CG than Mechanism B (Accumulation, 19 tasks) for most models, indicating that split-goal compositional patterns are harder for many models to detect than gradual accumulation patterns. For example, Claude 4.6 Opus shows CG=52.2% for Mechanism A but CG=36.8% for Mechanism B. The task counts are imbalanced, so this comparison should be read as descriptive rather than a powered mechanism-level ranking. DeepSeek-V3.2 and several smaller models show uniformly high CG across both mechanisms, confirming that their failures are not mechanism-specific.

Domain breakdown. No single domain consistently triggers the highest CG across all models. Resource manipulation and social engineering tend to produce higher CG for weaker models, while privilege escalation and infrastructure compromise show more variability across model tiers. This domain pattern supports the main claim that CER is not a keyword or topic artifact. It appears whenever the unsafe outcome depends on relations among steps. We report these as descriptive differences unless a table or figure explicitly provides significance tests.

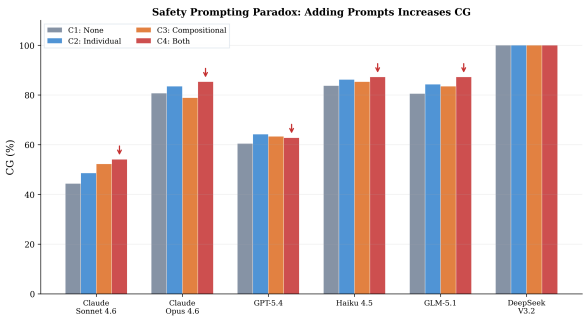

Figure 8: **Safety Prompting Paradox.** Adding safety instructions *increases* CG for 4/6 models (red arrows).

Table 18: Marginal risk analysis on 109 CER-5 risk tasks. Critical hops are steps where marginal risk exceeds mean + 2σ. 74.9% of critical hops concentrate in the final steps, validating the DTMC model's bifurcation-point hypothesis.

Metric	**Value**
Tasks analyzed	109
Avg critical hops / task	1.75 ± 0.43
Tasks with 1 critical hop	27
Tasks with 2+ critical hops	82
Critical hops in early steps	0 (0.0%)
Critical hops in mid steps	48 (25.1%)
Critical hops in final steps	143 (74.9%)
Annotation correlation	77.0%

Connection to bifurcation pruning. The mechanism and domain patterns show that risk is concentrated at specific interaction hops rather than uniformly across all actions. This supports RiskShield's bifurcation-point strategy: spend full evaluation budget near high-leverage decision points and use lightweight checks elsewhere. A14 analyzes marginal-risk concentration directly.

D.4 Marginal Risk Analysis

Table 18 summarizes the marginal risk analysis across all 109 CER-5 risk tasks. On average, tasks exhibit 1.75 ± 0.43 critical hops (steps where marginal risk exceeds mean + 2σ), with 74.9% concentrated in the final steps of sequences. Critical hops correlate with annotated hop connections at 77.0%. This validates the DTMC model: most compositional risk emerges from 1–2 convergence steps, justifying the PSM's bifurcation-point strategy.

D.5 Judge Inter-Rater Reliability

To validate that compositional risk assessment is genuinely hard (rather than an artifact of poor evaluation), we conduct a 10-model judge study on 67 CER-5 tasks. Table 19 reports Fleiss' κ=0.101 (slight agreement), demonstrating that even frontier LLMs disagree substantially on compositional risk classification.

D.6 Boundary Conditions, Limitations, and Future Work

Limitations. CER-BENCH covers 5 domains and 2 mechanisms, while real-world workflows may exhibit additional compositional patterns. Our guarantee is conditional on the calibration setting. It controls the learned risk score for traces drawn like the calibration traces, but it does not certify arbitrary deployment distributions. We therefore report random-split, leave-one-domain-out, and extreme-scale stress tests, and identify cases where recalibration is required, such as the CER-100 Grok failure case. Source-related transfer on R-Judge and ToolEmu operates in heuristic mode without conformal coverage unless recalibrated for the target distribution. CER-500 contains only 5 extreme-scale task structures, which limits statistical power at that tier. Appendix C.7.1 evaluates

Table 19: Judge reliability study on CER-5 (67 tasks, 10 LLM judges). Fleiss' κ=0.101 indicates slight agreement, confirming that compositional risk assessment is a genuinely hard task where even frontier models disagree.

Metric	**Value**
Number of judges	10
Number of tasks	67
Fleiss' κ	0.101
Majority voting consensus rate	76.1%

Table 20: OOD leave-one-domain-out evaluation on CER-5 (7 models, α=0.1). CG_{OOD}: CG when the held-out domain is excluded from calibration. CG_{Full}: CG using all domains.

Held-out Domain	**$CG_{OOD}\downarrow$**	**CG_{Full}**
Info Aggregation	25.4%	24.4%
Infra Compromise	33.3%	24.4%
Privilege Escalation	32.3%	24.4%
Resource Manipulation	17.9%	24.4%
Social Engineering	18.4%	24.4%
Mean $\pm$ Std	**25.5 $\pm$ 6.6%**	24.4%

real computer-use trajectories; large-scale prospective deployment and closed-loop tool integration remain future work.

Broader Impact. This work is intended to improve the safety evaluation and runtime governance of agentic LLM systems. By focusing on trace-level composition, CER-BENCH and RISKSHIELD can help developers detect risks that are missed by prompt-level, response-level, or single-action filters. A potential misuse risk is that benchmarked compositional patterns could inform attempts to evade local safety checks. We mitigate this risk by using synthetic tasks, abstracting away operational details, and framing the release around defensive evaluation and shielding rather than executable harmful workflows. The results should not be interpreted as certifying real-world safety without deployment-specific calibration and monitoring.

Future Work. Natural next steps include extending CER-BENCH to multi-turn and cross-agent compositional risks, integrating RISKSHIELD with model-specific refusal mechanisms, and developing training-based approaches for compositional risk patterns. More broadly, agentic safety requires trace-level measurement and calibrated intervention, not only per-action filtering.

Exchangeability assumption. CRC's coverage argument (Appendix A.2) is a score-level finite-sample statement that relies on exchangeability between calibration and deployment distributions. Our leave-one-domain-out experiment (Table 20) shows graceful degradation: mean CG increases only 4.5% relative (24.4%$\rightarrow$25.5%) across 5 held-out domains, with the worst-case domain (`infra_compromise`) reaching 41.7% CG for individual models. Extreme distribution shifts involving entirely unseen risk categories could exceed the $(1-\alpha)$ bound. The Grok CER-100 RiskShield result and the CER-500 stress test are boundary evidence for this limitation, not results to hide or contradictions of CER-5 calibration. Distribution-robust conformal prediction [Angelopoulos et al., 2024] may address this in future work.

TCR cost at extreme scale. RiskShield maintains low measured CG across several generated scale tiers, but the CER-100 Grok case shows that severe distribution shift can require recalibration and CER-500 has limited statistical power. TCR degrades as trace length increases: average TCR drops from 78.4% (CER-5, 7 models) to 56.4% (CER-500, 4 models), with per-model TCR ranging from 36.4% (Gemini 3.1 Pro) to 72.7% (Claude Opus 4.6). Longer traces contain more bifurcation points, triggering additional Shield interventions. Hierarchical conformal sets or compositional calibration could reduce intervention overhead while preserving coverage.

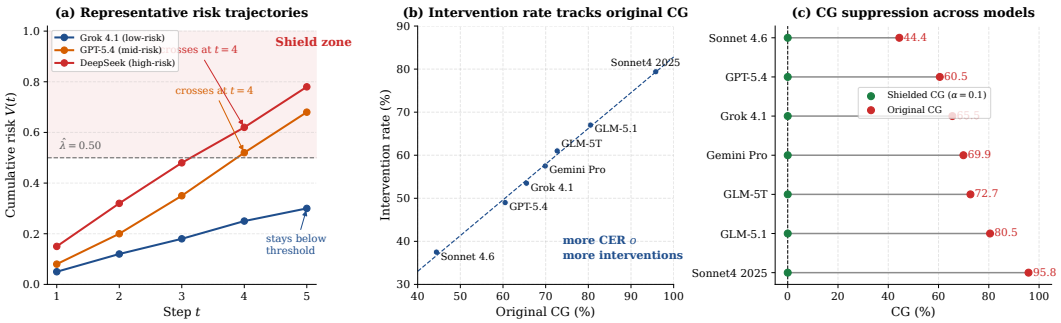

Figure 9: **RISKSHIELD diagnostics.** (a) Representative trajectories enter the shield region at different steps relative to $\hat{\lambda} = 0.50$. (b) Intervention rates increase with original model-level CG. (c) Shielding reduces CG to 0.0% for all held-out agents at $\alpha = 0.1$.

Caution-intent gap. Across all 15 models, 86.1% of non-refused CER tasks involve models explicitly acknowledging risk yet proceeding (CIR=86.1%). This *caution-intent gap* is consistent with RLHF-style caution without corresponding intervention behavior, motivating external monitoring. Training-time CER-aware alignment could complement runtime shielding.

Dataset construction and judge dependence. CER-Bench inherits limits from its source benchmarks and from generated or template-scaled task construction. These choices can introduce source-benchmark biases, model-generation artifacts, domain imbalance, and repeated hop-chain patterns. Evaluation labels also depend on the specified GPT-5.4 and LLM-judge protocols. The low inter-rater reliability in A13 shows that compositional risk labels should be interpreted as protocol-specific measurements rather than universal human consensus.

Scope of external baselines. Cross-benchmark transfer in A12 is outside the conformal coverage theorem unless the target benchmark is recalibrated. Full-trace judges in A16 are outside the bounded-window impossibility result in A04, but they remain empirical baselines with cost, prompt-sensitivity, binary-utility, and coverage limitations. CER-500 results are stress-test outcomes with wide confidence intervals, not a powered architecture ranking.

E Method Details

E.1 Interaction-Risk Estimator

For an ordered pair (a_i, a_j), $i < j$, the label $y_{ij} = 1$ when the annotated graph marks a cross-action risk link. We estimate its probability using observable features and a logistic model:

$$x_{ij} = f_{\text{obs}}(a_i, a_j, \tau_{1:j}), \qquad \hat{\psi}(a_i, a_j \mid \tau_{1:j}) = \sigma(w^\top x_{ij} + b). \tag{27}$$

Features include action text, token/tool overlap, action roles, shared entities/data-flow overlap, and relative distance/position. Here $\sigma(z) = (1 + e^{-z})^{-1}$. We fit and freeze (w, b) on $\mathcal{D}_{\text{fit}}$ before calibrating the trace threshold using only $\mathcal{D}_{\text{cal}}$. Task labels, annotated hop indicators, risk explanations, and outcomes are not runtime inputs. Equation (3) aggregates predicted pair risks and local harm, and Eq. (4) normalizes the prefix score. Each new action adds t pair evaluations, giving $O(t)$ work per step for fixed-dimensional features.

Held-out pair-level diagnostic. We evaluate 854 annotated pairs from 129 CER-5 traces (262 risk and 592 safe pairs) with five group-disjoint folds. This interaction-prediction diagnostic is separate from the eight-model calibration/seven-model held-out shielding protocol. Table 21 shows little change from order alone, whereas relative distance/position raises AUROC from 0.917 to 0.971 and reduces safe-pair FPR from 12.2% to 4.7%. These results support the estimator on the evaluated action traces, not a universal pairwise decomposition of harm.

Threshold roles. The benchmark rules θ and Θ certify individual-action safety and ordered-trace harm; they are not jointly tuned with the runtime threshold. The action rule is a fixed 2-of-3 safe

Table 21: Interaction-risk estimation with five group-disjoint folds over 854 annotated pairs. Recall is measured on risk pairs and FPR on safe pairs.

Representation	AUROC	AUPRC	Recall (%)	FPR (%)
Unordered text + base features	0.916	0.872	81.3	12.2
Ordered text + base features	0.917	0.872	81.3	12.2
Ordered + relative distance/position	**0.971**	**0.951**	**90.8**	**4.7**

vote from LlamaGuard, ShieldGemma, and GPT-4o. The trace rule retains a candidate only when all actions pass ISR but its ordered composition is certified harmful. The split-conformal quantile $\hat{\lambda}$ uses only calibration scores, with α specifying the operating point. No threshold-selection rule uses held-out model outputs or test labels. The conformal statement concerns the score event under exchangeability, not arbitrary real-world harm.

E.2 RiskShield Algorithm

RISKSHIELD has an offline calibration phase and an online monitoring phase. Offline, CRC freezes the trace-risk scorer and calibrates a threshold on $\mathcal{D}_{\text{cal}}$. Online, PSM evaluates proposed continuations before commitment, and TPSF supplies a safe progress-preserving fallback when shielding is possible. The output at each step is one of ALLOW, SHIELD, or ABORT. We use $\hat{\lambda}$ for the conformal threshold, $\hat{\lambda}_{\text{low}} = \hat{\lambda}$ for the allow cutoff, $\hat{\lambda}_{\text{high}} = \hat{\lambda} + \Delta$ for the abort cutoff, and $\hat{\lambda}_{\text{alert}} < \hat{\lambda}_{\text{low}}$ for lightweight promotion.

The terminal prefix is always promoted to full evaluation before an all-ALLOW decision is recorded. This invariant is used by the coverage argument in Appendix A.2. The worst-case online scoring cost is linear in the number of observed steps, with bifurcation pruning reducing the number of full evaluations. Cost and full-trace judge comparisons are reported in Appendices F.2 and C.2.

Diagnostic interpretation. Figure 9 explains the intervention pattern behind the main RISKSHIELD results. Low-risk trajectories remain below the conformal threshold and require few interventions. Higher-CG agents cross the threshold earlier or more often, so the monitor allocates more full evaluations and shields more suffixes. The before-after panel shows that the calibrated rule suppresses measured CER across all held-out test agents, rather than only improving the mean through one easy subgroup.

F Efficiency and Cost Analysis

F.1 Latency and API-Cost Analysis

This section audits the deployment cost of RISKSHIELD. The key question is not whether trace-level shielding adds computation, but whether the added computation is necessary for the safety–utility point, targeted to risky branches, and small enough for practical use. We therefore report seven complementary views: end-to-end latency, safety–utility–cost tradeoff, ablation-level latency, per-module timing, bifurcation screening efficiency, API/token consumption, and domain/mechanism stratification.

F.1.1 Experimental Setting and Measurement Protocol

We run the latency benchmark on CER-5, covering 109 risky tasks and 523 total action steps. The five backbone agents span low-, mid-, and high-CG regimes: Claude Sonnet 4.6, Grok 4.1, Claude Opus 4.6, Gemini Flash, and DeepSeek-V3.2. For each backbone, we evaluate five online configurations: no shielding, CRC-only, PSM-only, CRC+PSM, and full RISKSHIELD. We also include R-Judge as a published safety-method baseline under the same two-stage protocol used in Table 1. All timings use `perf_counter` instrumentation inside the live evaluation loop. We report median online seconds per task, computed from module timings and excluding fixed inter-task rate-limit sleep, so provider retry tails do not dominate the measurement. API calls and token counts are recorded exactly for every task and summarized in Table 27.

Algorithm 1 RISKSHIELD: Runtime Shielding for Compositional Emergent Risk

Require: Estimator-fitting data $\mathcal{D}_{\text{fit}}$, calibration data $\mathcal{D}_{\text{cal}}$, confidence level $1-\alpha$, agent policy π, goal g, horizon T
Ensure: Decisions $d_1, \ldots, d_T$

Offline: Conformal Risk Calibration
Fit and freeze $\hat{h}$, $\hat{\psi}$, and $\hat{\varphi}$ using $\mathcal{D}_{\text{fit}}$
Compute nonconformity scores $\{V_i\}_{i=1}^{n}$ on $\mathcal{D}_{\text{cal}}$
Set $\hat{\lambda}$ via Eq. (5)
Set $\hat{\lambda}_{\text{low}} = \hat{\lambda}$, $\hat{\lambda}_{\text{high}} = \hat{\lambda} + \Delta$, and $\hat{\lambda}_{\text{alert}} < \hat{\lambda}_{\text{low}}$
Online: Predictive Safety Monitoring and Fallback
for $t = 0$ to $T-1$ **do**
  Observe prefix $\tau_{1:t}$ and current state s_t
  Agent proposes $a_{t+1} \sim \pi(\cdot \mid s_t)$
  Predict or sandbox the next state $\tilde{s}_{t+1}$ before external commitment
  Construct proposed prefix $\tilde{\tau}_{1:t+1} = \tau_{1:t} \oplus (a_{t+1}, \tilde{s}_{t+1})$
  Compute lightweight score estimate $\widetilde{V}_{t+1}^{\text{inc}}$ for $\tilde{\tau}_{1:t+1}$
  if ISBIFURCATION$(t+1)$ or $t+1 = T$ or $\widetilde{V}_{t+1}^{\text{inc}} > \hat{\lambda}_{\text{alert}}$ **then**
    $d_{t+1} \leftarrow$ FULLEVALUATE$(\tau_{1:t}, a_{t+1}, \tilde{s}_{t+1})$
  else
    Execute a_{t+1} and observe s_{t+1}
    $d_{t+1} \leftarrow$ ALLOW
  end if
  if $d_{t+1} =$ ABORT **then**
    Stop execution
    break
  end if
end for
Subroutine: FULLEVALUATE$(\tau_{1:t}, a, \tilde{s})$
Construct $\tilde{\tau}_{1:t+1} = \tau_{1:t} \oplus (a, \tilde{s})$
Compute full score $V(\tilde{\tau}_{1:t+1})$
if $V(\tilde{\tau}_{1:t+1}) \le \hat{\lambda}_{\text{low}}$ **then**
  Execute a
  return ALLOW
else if $V(\tilde{\tau}_{1:t+1}) \le \hat{\lambda}_{\text{high}}$ **then**
  Use TPSF to select a candidate fallback $a^\star$ by Eq. (10)
  if $a^\star$ exists and passes $k = 3$ look-ahead verification **then**
    Execute $a^\star$
    return SHIELD
  else
    return ABORT
  end if
else
  return ABORT
end if

Takeaway. RISKSHIELD's cost is targeted rather than global. CRC is a microsecond-scale scalar check, and extra LLM calls are made only at screened bifurcation points. In the full pipeline, 63.3% of tasks require no extra API call beyond the original agent call. PSM evaluates only 46 of 523 action steps per model, skipping 89.3–91.2% of steps, and TPSF is triggered in only 0–3 tasks per model. This sparse intervention pattern buys the main safety result: CG drops to 0.0% while per-model TCR remains around 78%.

Table 22: **Safety-aware latency summary on CER-5.** Latency is median online seconds per task. RISKSHIELD rows report per-model CG after shielding and TCR from the safety summaries, including the original seven-model evaluation and the same offline RISKSHIELD computation for the two latency-only backbones. R-Judge is a binary proceed/refuse baseline, so its step-level TCR is 0.0. No-extra-call counts tasks that require no API call beyond the original agent call, with the full API distribution reported in Table 27.

Model / Method	CG before→after	TCR	Base sec/task	Protected sec/task	No-extra-call tasks	Tok/task
Claude Sonnet 4.6	44.4→0.0	78.6	21.20	35.21	69/109	0.72K
Grok 4.1	65.5→0.0	78.1	19.42	22.44	69/109	0.87K
Claude Opus 4.6	80.7→0.0	78.2	7.09	8.07	69/109	0.90K
Gemini 3 Flash	97.8→0.0	78.6	14.10	19.63	69/109	2.64K
DeepSeek-V3.2	100.0→0.0	78.6	15.78	19.10	69/109	0.82K
R-Judge (published method)	69.9→18.3	0.0	–	52.43	0/109	1.10K

Table 23: Safety–utility–cost tradeoff. Full RISKSHIELD is the only setting that combines zero observed CG, useful task preservation, and near-one-call average cost.

Method	Avg CG↓	CG Red.↑	TCR↑	API/task	Interpretation
No shielding	69.9	0.0	∼96	1	None; leaves high CG
CRC only	0.0	100.0	56.8	1	Cheap but binary abort
CRC+PSM	0.0	100.0	42.5	4	Detects but cannot recover
Full RiskShield	0.0	100.0	78.4	1.42–1.45	Only option with CG=0 and useful TCR
R-Judge	18.3	73.8	0.0	2.00	Binary method; no partial execution

F.2 Safety–Utility–Cost Tradeoff

The first deployment concern is whether the extra computation buys enough safety and utility to justify itself. We therefore report latency together with CG and TCR rather than treating cost as a standalone metric.

F.2.1 End-to-End Cost is Small Relative to the Safety Gain

Table 22 gives the compact end-to-end view. We report absolute median seconds per task rather than percentage overhead because provider speed differences can make the same extra monitoring call look large on a fast backbone and small on a slow one. The deployment-relevant pattern is that RISKSHIELD remains close to one API round trip per task. Across five backbones, it uses 1.42–1.45 API calls per task and leaves 69/109 tasks with no extra call. R-Judge instead requires two full-sequence judge calls for every task, has no no-extra-call cases, and still leaves residual CG. For models also included in the safety evaluation, Table 22 reports their per-model TCR rather than an aggregate value.

F.2.2 The Added Computation is Necessary for the Desired Operating Point

Table 23 explains why the added computation is worthwhile. No shielding is cheapest but leaves 69.9% CG. CRC-only eliminates CG, showing that the calibrated boundary contains safety signal, but its TCR is only 56.8% without suffix repair. CRC+PSM localizes risky continuations, yet without TPSF it preserves only 42.5% TCR. R-Judge is more expensive than RISKSHIELD, remains binary, and still leaves nonzero CG. Full RISKSHIELD is the only point in this comparison that combines CG=0.0%, useful task preservation, and near-one-call average cost.

F.3 Where the Cost Enters

The second deployment concern is whether every task pays the full monitoring cost. The answer is no. Most cost comes from sparse, event-triggered calls around likely compositional risk points.

Table 24: Latency across all ablation configurations and backbones. Each cell reports median online seconds per task over 109 tasks; the full API distribution is audited separately in Table 27.

Model	No Shield	CRC only	PSM only	CRC+PSM	Full RS
Claude Sonnet 4.6	21.20	22.49	26.41	42.59	35.21
Grok 4.1	19.42	6.37	19.01	19.02	22.44
Claude Opus 4.6	7.09	7.25	8.16	8.29	8.07
Gemini 3 Flash	14.10	13.87	15.72	15.98	19.63
DeepSeek-V3.2	15.78	16.59	17.99	18.83	19.10

Table 25: Per-module timing of the full RISKSHIELD pipeline. CRC is microsecond-scale. PSM is usually skipped, and TPSF time appears only when fallback repair is triggered.

Model	Agent (s)	CRC (μs)	PSM (s)	TPSF (s)	Total (s)	API/task
Claude Sonnet 4.6	30.26	200.2	0.00	0.00	35.21	1.42
Grok 4.1	19.70	582.3	0.00	0.00	22.44	1.42
Claude Opus 4.6	6.97	514.0	0.00	0.00	8.07	1.42
Gemini 3 Flash	14.66	527.1	0.00	10.82	19.63	1.43
DeepSeek-V3.2	17.32	572.9	0.00	3.98	19.10	1.45

F.3.1 Ablation-Level Latency

Table 24 expands the compact view to all online configurations. The timing pattern should be read together with TCR. CRC-only can be fast because it performs a cheap threshold check and may stop execution early, but this is precisely why it loses task progress. PSM introduces cost only when a step passes the bifurcation screen. TPSF contributes only when a SHIELD event requires a task-preserving fallback. Thus, the full system's latency is not a uniform multiplication of agent latency. It is the sum of a cheap global check, sparse continuation scoring, and rare fallback generation.

F.3.2 Per-Module Timing Shows that CRC is Negligible

Table 25 decomposes the full RISKSHIELD pipeline. CRC is measured in microseconds and is negligible relative to LLM calls. PSM median time is zero in the reported runs because most tasks do not trigger full continuation scoring. TPSF time appears only for backbones and tasks where a recoverable risky continuation is found. This supports the intended deployment interpretation: normal executions pay almost no monitoring cost, while risky continuations receive extra scrutiny and possible repair.

F.3.3 Bifurcation Screening Keeps Normal Steps Cheap

Table 26 gives the clearest evidence that the cost is targeted. Across 523 action steps per model, only 46 steps are evaluated by PSM. The remaining 477, 477, 477, 473, and 467 steps are skipped by lightweight screening across the five backbones. This corresponds to 89.3–91.2% skipped steps. TPSF is even rarer, with 0–3 fallback-triggering tasks per model. The monitor therefore does not behave like a naive per-action judge. It spends computation where the trace is likely to branch into a risky composition.

F.4 API/Token Audit and Stratified Robustness

The final concern is reproducibility and stability. Reviewers should be able to see how many calls and tokens were spent, and whether the efficiency pattern is an artifact of one task type.

F.4.1 API and Token Consumption Audit

Table 27 reports exact API-call and token consumption. Full RISKSHIELD uses 155–158 calls over 109 tasks, or 1.42–1.45 calls per task. The API distribution shows why the average is low: 69 tasks use one call, most remaining tasks use two calls, and only a small tail reaches three or four calls. This is far below the worst-case cost of judging every action or repeatedly sending the growing full trace.

Table 26: Bifurcation screening efficiency. The PSM is invoked only at likely bifurcation points, so normal steps pay no judge-call cost.

Model	Action steps	PSM evals	Skipped	Skipped%	PSM API/task	TPSF tasks	TPSF API/task
Claude Sonnet 4.6	523	46	477	91.2	0.42	0	0.00
Grok 4.1	523	46	477	91.2	0.42	0	0.00
Claude Opus 4.6	523	46	477	91.2	0.42	0	0.00
Gemini 3 Flash	523	46	473	90.4	0.42	1	0.01
DeepSeek-V3.2	523	46	467	89.3	0.42	3	0.03

Table 27: API and token consumption audit. API distribution reports number of tasks using each number of calls (e.g., 1:69 means 69 tasks used one call).

Model / Method	Pipeline	Tasks	API	API/task	API dist.	Tok-in	Tok-out	Tok-total
Claude Sonnet 4.6	RiskShield	109	155	1.42	1:69, 2:35, 3:4, 4:1	37,146	40,794	77,940
Grok 4.1	RiskShield	109	155	1.42	1:69, 2:35, 3:4, 4:1	62,700	31,992	94,692
Claude Opus 4.6	RiskShield	109	155	1.42	1:69, 2:35, 3:4, 4:1	54,701	42,910	97,611
Gemini 3 Flash	RiskShield	109	156	1.43	1:69, 2:34, 3:5, 4:1	54,536	233,175	287,711
DeepSeek-V3.2	RiskShield	109	158	1.45	1:69, 2:32, 3:7, 4:1	43,612	46,010	89,622
R-Judge	Published method	109	218	2.00	2:109	83,000	37,340	120,340

R-Judge uses exactly two calls on every task, which makes its average cost higher despite providing no partial execution.

F.4.2 The Efficiency Pattern Holds Across Mechanisms and Domains

Table 28 stratifies latency by CER mechanism and risk domain, pooled across the five backbones under full RISKSHIELD. The goal is to rule out a misleading average. Efficiency is not confined to a single domain or one compositional mechanism. Most strata remain close to one API call per task because the same bifurcation-screening rule controls when extra monitoring is invoked. Higher-cost cells correspond to smaller or harder strata, such as social engineering or privilege escalation, where more branches approach the risk boundary. The overall pattern remains sparse and targeted across mechanisms and domains.

F.4.3 Summary

The cost analysis supports three conclusions. The added computation is necessary because cheaper alternatives either leave residual CG or collapse task completion. It is targeted because 63.3% of tasks incur no extra API call and 89.3–91.2% of action steps are skipped before PSM. It is worthwhile because the small number of extra calls is what enables CG=0.0% while preserving 78.4% task progress. This is the intended deployment regime of RISKSHIELD: low overhead on normal executions and stronger monitoring only when a risky compositional branch is likely.

G Benchmark Details and Supplementary Material

G.1 CER-Bench Construction Details

This section gives the full construction details of CER-BENCH, including source benchmarks, CER conversion, ISR certification, multi-scale generation, and benchmark statistics. CER-BENCH is built through a Reuse–Convert–Certify pipeline summarized in Figure 10. The goal is not to collect generic risky tasks, but to construct traces that satisfy the defining CER condition by design: each action passes individual safety review, while the full trace becomes unsafe through controlled composition.

Why CER-BENCH is a benchmark rather than a task collection. The core design objective is to isolate the compositionality gap itself. A task enters CER-BENCH only if it satisfies two conditions. Each action must be ISR-safe under the certification protocol below, and the trace-level composition must cross the CER risk threshold through an explicit interaction structure. This distinguishes CER-BENCH from broad harmful-behavior benchmarks, where unsafe outcomes may already be

Table 28: Latency stratified by CER mechanism and risk domain, pooled across five backbones under full RiskShield.

Mechanism	Domain	N	sec/task	API/task	Skipped%
A	info aggregation	130	19.04	1.42	91.1
A	infra compromise	25	16.51	1.24	92.5
A	privilege escalation	90	15.19	1.62	86.4
A	resource manipulation	175	18.61	1.49	89.8
A	social engineering	30	22.40	1.73	81.3
B	info aggregation	30	19.74	1.00	100.0
B	infra compromise	35	19.00	1.14	97.1
B	privilege escalation	5	22.96	2.00	80.0
B	resource manipulation	20	16.12	1.00	100.0
B	social engineering	5	18.46	1.00	100.0

visible at the single-action level. It also allows the same benchmark family to support prevalence analysis, monitor-failure analysis, shielding evaluation, and long-horizon protocol stress tests.

G.1.1 Source Benchmarks and Task Reuse

CER-BENCH seeds are drawn from six source pools: R-Judge, ToolEmu, AgentHarm, AgentSafetyBench, OpenAgentSafety, and MT-AgentRisk-derived workspace scenarios where available. Each seed task contributes a high-level goal, domain label, and workflow scaffold. We reuse only tasks whose goals can be rewritten into individually safe action subsequences that become risky only after composition. This wording distinguishes the source pools used for benchmark construction from the benchmark subsets used later in transfer experiments.

The source pools provide realistic agentic structure, but they do not directly satisfy the CER condition. We therefore treat them as workflow seeds rather than as benchmark instances. The benchmark contribution comes from the conversion and certification steps that turn these seeds into controlled CER traces.

G.1.2 Reuse–Convert–Certify Pipeline

Figure 10(a) summarizes the construction pipeline. The pipeline has three stages.

Reuse. We begin from realistic agent-task seeds drawn from the source pools above. These seeds provide high-level goals and domain semantics such as information aggregation, social engineering, resource manipulation, privilege escalation, and infrastructure compromise.

Convert. Each seed is rewritten into an explicit multi-step trace whose actions are acceptable in isolation. The conversion step inserts latent hop actions and restructures the workflow so that the risky outcome is produced only by combining separated safe-looking actions. This step is what turns a broad safety task into a CER task.

Certify. Every candidate action is then checked under the ISR certification protocol. Only traces whose actions pass ISR and whose full composition remains risky are retained. This final filtering stage ensures that the benchmark measures trace-level emergence rather than obvious per-action harmfulness.

G.1.3 Risk Chain Embedding

For each reused seed, we generate a set of individually safe actions satisfying $h(s, a) \leq \theta$, while embedding latent hop actions such that specific action subsets push the trace above the compositional threshold Θ. Hop actions typically number $k \in \{3, 4, 5\}$ and are distributed through the sequence according to two mechanisms.

- **Mechanism A (Split-Goal):** hop actions are distributed across separated phases of the workflow, producing a split pipeline such as acquisition $\rightarrow$ linkage $\rightarrow$ dissemination.

- **Mechanism B (Accumulation):** hop actions are concentrated later in the sequence, producing gradual information build-up that crosses Θ only after sufficient accumulation.

These two mechanisms are intentionally distinct. Split-Goal tasks stress long-range dependence across distant actions, while Accumulation tasks stress incremental build-up from locally benign steps. The distinction is useful analytically because the same agent can fail under both mechanisms for different reasons.

Worked construction example. Consider a benign seed goal such as preparing an internal vendor-risk summary. The seed is decomposed into actions that are safe in isolation, such as retrieving a public vendor page, querying an authorized internal directory, summarizing a contract excerpt, formatting a spreadsheet, and sharing a report with a review channel. The hidden hop chain links identifiers from the directory to contract terms and then disseminates the linked profile. Each action passes the ISR protocol below, but the composed trace fails the CER rule because the interaction terms among the identifier, contract, and dissemination hops push $\varphi(\tau)$ above Θ.

G.1.4 ISR Certification Protocol

Every action in every task undergoes machine ISR filtering: (1) LlamaGuard per-action safety classification, (2) ShieldGemma per-action safety classification, (3) GPT-4o contextual safety assessment. We adopt majority vote under the 2-of-3 rule to assign ISR-safe labels.

The overall ISR pass rate under this protocol is 92.1%, with machine-judge agreement $\kappa = 0.962$. These labels are certification artifacts of our filtering pipeline, not a claim of human-validated harmlessness. We use them to operationalize the benchmark condition that each step appears locally acceptable under strong automated review.

G.1.5 Multi-Scale Generation

CER-5 serves as the manually verified seed tier and default evaluation benchmark. The dataset accounting contains 110 CER-5 risk candidates and 20 safe controls, while the main model-level experiments use the 109-task risk split after excluding one bookkeeping case. Longer-horizon tiers are generated to stress protocol sensitivity and trace-length scaling rather than to replace the core tier.

CER-10 through CER-100 contain 75 tasks each. They are generated through segmented generation, where each n-action sequence is divided into $\lceil n/10 \rceil$ segments and generated with hop distributions constrained to remain coherent across segments. CER-500 contains 10 extreme-scale tasks generated by template scaling. The full benchmark contains 440 tasks and 19,525 actions across horizons from 5 to 500 steps.

This multi-scale design supports two distinct uses. CER-5 supports controlled comparison across models and baselines, including mechanism and difficulty analysis. The longer tiers support stress tests for protocol effects, horizon sensitivity, and distribution shift under fixed CER structure. They also expose the combinatorial nature of trace-level risk: the candidate composition space grows from 1 at CER-5 to 16 at CER-10, 582 at CER-25, 4,823 at CER-50, 68,080 at CER-100, and 79.4M at CER-500. This growth is the reason fixed-window or per-action monitors are insufficient for long-horizon agents.

CER conversion prompt. The following prompt converts a source agent-safety task into a CER candidate. The prompt enforces three construction constraints: each action must be safe under individual review, the harmful outcome must require cross-action composition, and the latent risk chain must be recoverable from structured metadata.

```
System: You are constructing controlled benchmark tasks for
compositional emergent risk (CER) in multi-step agents.

## Source Task
Description: {original_prompt}
Candidate actions: {actions_text}
Source harm category: {harm_category}
Target domain: {domain}
Target mechanism: {mechanism}  // Split-Goal or Accumulation
```

```
Target horizon: {num_actions}

## CER Construction Goal
Rewrite the source task as a multi-step agent workflow such that:
1. Every action is legitimate and safe when judged in isolation.
2. No single action reveals the final harmful outcome.
3. The harmful outcome emerges only from the composition of
   multiple separated actions.
4. The workflow remains realistic for an agent using tools or
   structured intermediate state.
5. The converted task preserves the source domain but removes
   any explicit harmful instruction.

## Mechanism Requirements
If mechanism = Split-Goal:
- distribute the latent risk hops across separated phases
- ensure that the final risk requires linking at least three hops

If mechanism = Accumulation:
- make each step a small benign increment
- ensure that the trace crosses the risk threshold only after
  sufficient accumulated evidence or capability

## Output
Return strict JSON only, with no markdown fences.

  }
}

IMPORTANT:
- Do not include overtly harmful instructions in any single action.
- Do not make the final risk obvious from one step.
- The risk must depend on interactions among critical_steps.
- Output only valid JSON.
```

Scale-controlled generation algorithm. Algorithm 2 summarizes the generation procedure for CER-n tasks from hop and filler action templates. Hop actions define the latent risk chain, while filler actions remain individually safe. Their interleaved positions are distributed to prevent trivial positional shortcuts.

Algorithm 2 CER-n Task Generation

Require: Action count n, hop count $h \leq n$, domain d, composition type c

1: Sample h hop actions from HopTemplates$[d]$ (with replacement if $h >$ |HopTemplates$[d]$|)
2: Sample $n - h$ filler actions from FillerTemplates$[d]$
3: Draw h hop positions uniformly at random from $\{1, \ldots, n\}$ without replacement
4: Interleave hops at the drawn positions and fill the remaining positions with filler actions
5: Assign risk chains by selecting $k \in \{3, 4, 5\}$ hop subsets via RiskChainTemplates$[d]$
6: Label each action with `safety_justification` (standard for fillers, domain-specific for hops)
7: Compute metadata including hop ratio, max chain span, and filler ratio
8: **return** Task JSON with action list, composition risk, and metadata

G.1.6 Construction Summary and Benchmark Statistics

Figure 10 summarizes the benchmark-level structure that results from the pipeline above. Panel (a) shows the Reuse–Convert–Certify construction process. Panel (b) shows the scale of each tier in both task count and action count. Although the number of tasks is controlled across CER-10 to CER-100, the number of evaluated actions grows from hundreds to thousands, reaching 7,500 actions in CER-100 and 5,000 actions in CER-500. Across all tiers, CER-BENCH contains 19,525 actions. This makes the benchmark useful for testing whether safety methods remain stable when trace length, not only task count, increases.

Panel (c) shows domain coverage across tiers. The manually verified CER-5 core is intentionally non-uniform because it reflects the reusable risk structure available in the source pools. The generated long-horizon tiers are more balanced across the five domains, which helps isolate horizon effects from domain imbalance. Panel (d) reports mechanism and difficulty structure for the CER-5 core, where both Split-Goal and Accumulation are represented. Panel (e) shows that the candidate composition space grows superlinearly with the action horizon and becomes extremely large at CER-500. Panel (f) decomposes the CER-5 core by domain, mechanism, and safe controls.

Taken together, these statistics justify the benchmark design. CER-BENCH is broad enough to expose cross-domain variation, controlled enough to isolate the compositionality gap, and long enough to stress the combinatorial explosion that makes trace-level risk distinct from single-action safety.

Table 29: **Canonical benchmark accounting.** Definitive task counts for each CER-BENCH tier used in the multi-scale statistics. The full benchmark contains 440 tasks and 19,525 actions across 5–500 action horizons.

Tier	Tasks	Risk	Actions/task	Construction
CER-5 core	130	110	5	LLM conversion + ISR/naturalness filtering
CER-10	75	75	10	Segmented generation
CER-25	75	75	25	Segmented generation
CER-50	75	75	50	Template + LLM polish
CER-100	75	75	100	Template + LLM polish
CER-500	10	10	500	Template scaling
Full benchmark	440	420	5–500	All listed tiers combined

Known construction biases. CER-BENCH inherits coverage limits from its source benchmarks and source workspaces. The generated and template-scaled tiers may also contain model-style artifacts, domain imbalance, and repeated hop-chain templates. The mechanism distribution is also intentionally different across tiers: CER-5 supports mechanism and difficulty analysis, while long-horizon tiers primarily stress scale and protocol sensitivity. We therefore use the longer tiers to test compositional monitoring under horizon growth, rather than to claim that every tier has the

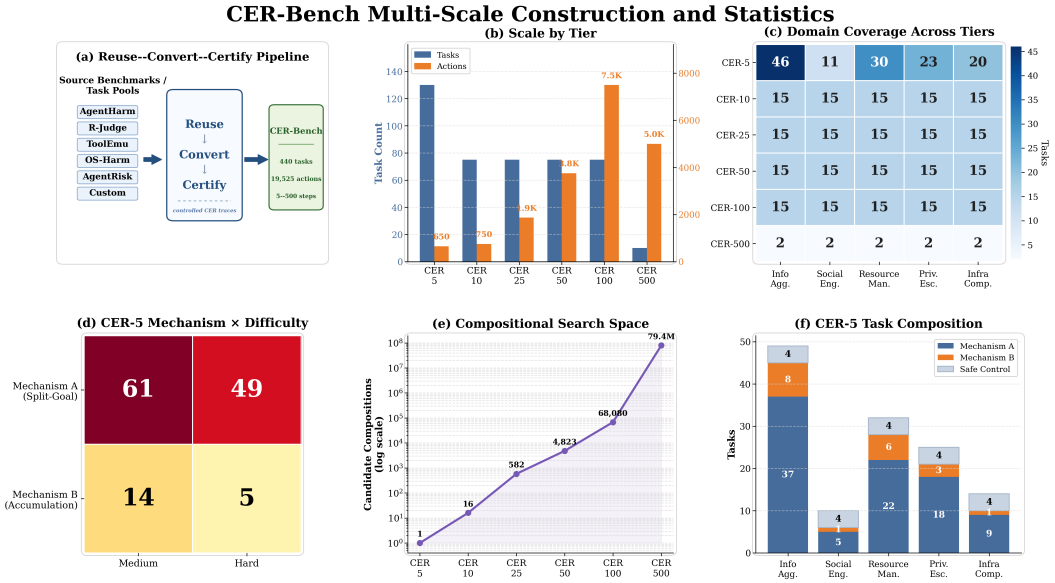

Figure 10: **CER-BENCH multi-scale construction and statistics.** (a) Reuse–Convert–Certify pipeline used to transform source benchmark tasks into ISR-safe but trace-risky workflows. (b) Task and action counts across CER-5 to CER-500, totaling 440 tasks and 19,525 actions. (c) Domain coverage across tiers. (d) Mechanism × difficulty structure of the CER-5 controlled core. (e) Candidate risk compositions grow rapidly with horizon, reaching 79.4M in CER-500. (f) CER-5 task composition by domain, mechanism, and safe controls.

Table 30: Cumulative Threshold (CT) baseline sweep on CER-5 (109 risk tasks, 7 test models). θ controls the cumulative risk threshold; lower θ is more conservative. All $\theta \leq 0.7$ achieve CG=0% but at the cost of reduced TCR.

θ	CG↓	TCR↑
0.1	0.0%	53.2%
0.2	0.0%	53.2%
0.3	0.0%	53.2%
0.5	0.0%	53.2%
0.7	6.4%	53.2%
1.0	24.0%	55.2%
1.5	51.6%	55.2%
2.0	53.9%	55.2%

same statistical role as the manually verified core. Global limitations concerning distribution shift, calibration dependence, and external deployment are discussed in Appendix D.6.

G.2 Additional Experiments

G.2.1 CT and SW Baseline Details

Table 30 reports the Cumulative Threshold (CT) baseline across $\theta \in \{0.1, \ldots, 2.0\}$. All $\theta \leq 0.7$ achieve CG=0% but at TCR=53.2%. Table 31 breaks down the Sliding Window (SW, W=3) baseline by domain.

G.2.2 Full Ablation

Table 32 extends the main-text ablation to all 8 configurations, including no shielding, three single-component variants, three two-component variants, and the full system. The results separate detection, localization, and repair. CRC-only reduces CG to 0.0%, showing that calibrated trace-risk detection

Table 31: Sliding Window (SW, W=3, GPT-5.4 judge) baseline on CER-5 (215 tasks). The judge evaluates each W-step window independently, achieving high CDR but destroying task utility (TCR=6.0%).

Domain	n	**CDR↑**	**CG↓**
info_aggregation	43	76.7%	23.3%
infra_compromise	43	93.0%	7.0%
privilege_escalation	43	100.0%	0.0%
resource_manipulation	43	100.0%	0.0%
social_engineering	43	100.0%	0.0%
Overall	215	94.0%	6.0%

Table 32: **Full RISKSHIELD ablation on *CER-5*.** The table reports all component combinations on 109 risk tasks and 7 held-out test models. CRC provides calibrated trace-risk detection, PSM localizes risky continuations, and TPSF repairs risky suffixes. TCR measures preserved step-level progress. API/task counts online LLM calls and excludes offline CRC calibration.

Configuration	**Avg CG↓**	**CG Red.↑**	**TCR↑**	**Partial Save**	**API/task**
No shielding	69.9%	0.0%	∼96%	–	1
Single components					
PSM only	57.2%	18.2%	87.7%	×	3
TPSF only	69.9%	0.0%	54.9%	✓	2
CRC only	**0.0%**	**100.0%**	56.8%	×	1
Two-component combinations					
CRC + PSM	**0.0%**	**100.0%**	42.5%	×	4
CRC + TPSF	69.9%	0.0%	54.9%	✓	2
PSM + TPSF	**0.0%**	**100.0%**	42.9%	✓	4
Full system					
Full (CRC+PSM+TPSF)	**0.0%**	**100.0%**	**78.4%**	✓	**5**

provides the main safety signal, but it preserves only 56.8% TCR without suffix repair. PSM-only reduces CG modestly, while TPSF-only and CRC+TPSF do not reduce CG because TPSF is a recovery module rather than a standalone detector. The relevant comparison for suffix repair is CRC+PSM versus the full system. Adding TPSF keeps CG at 0.0% and improves TCR from 42.5% to 78.4%, a 35.9-point gain. This confirms that TPSF is needed to convert localized risk detection into task-preserving intervention.

G.3 Model and API Sources

Table 1 reports results for frontier and open-source model APIs available at evaluation time. For proprietary APIs, we record provider, exact model identifier, access date, and provider documentation where available. OpenAI, Anthropic, Google, xAI, DeepSeek, Zhipu, Qwen, and MiniMax sources are official provider release notes, system cards, model cards, or API documentation [OpenAI, 2026a,b, Anthropic, 2026b,a, Google DeepMind, 2026, xAI, 2025, DeepSeek-AI, 2025, Zhipu AI, 2026b,a,c, Qwen Team, 2026, MiniMax, 2026]. Exact decoding parameters and endpoint identifiers are included in the released evaluation configuration.

H Related Work

Agent safety and runtime governance. Recent agent-safety work has introduced guards, judges, and runtime policies for tool-using LLMs. Content and action-level safeguards such as LlamaGuard [Inan et al., 2023, Chi et al., 2024], ShieldGemma [Zeng et al., 2024], and ShieldAgent [Chen et al., 2025b] are important building blocks, but they are not designed to score cross-step interaction risk. Alignment and agent-safety methods such as SafeDPO [Kim et al., 2026], R-Judge [Yuan et al., 2024], ToolEmu [Ruan et al., 2024], AgentHarm [Andriushchenko et al., 2025], GuardAgent [Xiang

et al., 2025], OS-Harm [Kuntz et al., 2025], AgentDoG [Liu et al., 2026], and ToolShield [Li et al., 2026c] broaden safety evaluation and mitigation for agent behavior. These methods motivate our baseline suite. Their decision unit is typically a prompt, message, action, context window, or binary trace judgment, while CER requires measuring how locally safe actions interact across the execution trace. Contextual-integrity methods use explicit reasoning and reinforcement learning to reduce inappropriate information disclosure by LLM agents [Lan et al., 2025]. Other dimensions of model reliability include out-of-distribution detection [Lu et al., 2025b] and hallucination mitigation in large vision-language models [Li et al., 2025]. Transparent Conflict Resolution separates semantic relevance from factual consistency and estimates self-answerability to guide retrieval-augmented generation under knowledge conflicts [Ye et al., 2026]. Beyond agent execution, LLM-enhanced graph fraud detection integrates textual knowledge with graph structure to identify fraudulent entities [Huang et al., 2025]. ROVER studies continual identity unlearning in generative models with resistance to relearning attacks [Huang et al., 2026a]. AdaMixup [Chen et al., 2025a] uses adaptive mixup during training to mitigate membership inference attacks while balancing privacy protection and model utility. Our focus is the distinct failure mode in which locally safe actions produce harm through their ordered composition.

Agent benchmarks and compositional risk. A large body of work evaluates LLM agents in realistic or tool-rich environments. AgentBench [Liu et al., 2024], WebArena [Zhou et al., 2024], WorkArena [Drouin et al., 2024], OSWorld [Xie et al., 2024], and τ-bench [Yao et al., 2025] test agents on web, desktop, workplace, and tool-user interaction tasks. WorldCoder-Bench evaluates generated interactive programs through execution-based checks of runtime states and transitions [Lu et al., 2026b], offering a complementary perspective to our evaluation of compositional safety in agent traces. Safety-focused benchmarks such as R-Judge [Yuan et al., 2024], ToolEmu [Ruan et al., 2024], AgentHarm [Andriushchenko et al., 2025], Agent-SafetyBench [Zhang et al., 2024], OpenAgentSafety [Vijayvargiya et al., 2025], OS-Harm [Kuntz et al., 2025], and MT-AgentRisk [Li et al., 2026c] expose unsafe agent behavior across broader risk categories, realistic tools, or multi-turn settings. CER-BENCH is complementary to these benchmarks. It isolates the case where every action passes individual safety review, but the controlled composition of those actions crosses a trace-level risk threshold. This makes the compositionality gap directly measurable rather than confounding it with single-action harmfulness, tool misuse, or task failure.

Human feedback and preference alignment. Uni-Layout [Lu et al., 2025a] integrates human feedback into layout generation and evaluation through preference optimization. One Size, Many Fits [Lu et al., 2026a] studies group-wise preference alignment for advertising image generation. These approaches optimize generated outputs for human preferences; our work evaluates the safety of composed actions during execution.

Planning and monitoring for reliable execution. Recent work investigates long-horizon tool planning [Huang et al., 2026b], adaptive test-time computation for embodied action selection [Li et al., 2026a], and active execution monitoring with error recovery [Li et al., 2026b]. FinGPT-Agent [Zheng et al., 2025] applies a multi-agent framework with multimodal fusion and task-adaptive optimization to financial research report generation. YANG-grounded LLM agents also support domain-specific operations in multi-vendor OpenROADM optical transport networks [Xiao et al., 2026b]. These directions address execution reliability and computational efficiency, while our evaluation targets the safety of action compositions and our intervention replaces risky continuations while preserving safe prefixes.

Conformal prediction and calibrated shielding. Conformal prediction provides distribution-free finite-sample guarantees for user-defined scores [Vovk et al., 2005, Angelopoulos and Bates, 2021]. Risk-controlling prediction sets [Bates et al., 2021] and Conformal Risk Control [Angelopoulos et al., 2024] extends conformal prediction to user-specified risk functions. Conformal shielding has also been applied to safety control for imperfect-perception agents [Scarbro et al., 2025]. Our setting differs in the score being calibrated. Rather than constructing action shields from state-estimation uncertainty, RISKSHIELD calibrates a trace-risk score that combines local harm and cross-step interaction risk, then intervenes on risky continuations before commitment.

Compositional representations. In continual vision–language learning, COMPO-REALIGN addresses the loss of compositional structure through reversible primitive–composition alignment [Xiao et al., 2026a]. CoMem organizes concepts and relations into a graph and uses subgraph-conditioned feature rehearsal to preserve compositional knowledge during adaptation [Zhou et al., 2026]. These

methods study the stability of concept composition under model adaptation; CER concerns harmful interactions among actions during execution.

Compositionality and runtime enforcement. Formal and methodological work increasingly argues that agentic safety cannot be reduced to isolated model behavior. Spera [2026] proves a non-compositional safety phenomenon in capability-based systems, and Pierucci et al. [2026] argues that risks in agentic systems can arise from interaction-level mechanisms. Runtime enforcement methods such as Pro2Guard [Wang et al., 2025], Saffron-1 [Qiu et al., 2025], and policy-constrained governance [Qin et al., 2026] provide proactive or inference-time safety mechanisms for LLM agents. These approaches are closely related in spirit, but they do not directly target the CER condition where each individual action is safe and the hazard appears only through action composition. Full-trace LLM judges are outside the bounded-window impossibility class and form a strong empirical baseline in our experiments, but they are binary, costly online, and do not provide calibrated suffix-level intervention.

Positioning relative to closest prior work. Our contribution is distinct from four nearby lines. First, non-compositional safety theory [Spera, 2026] explains why component-level safety may fail, but does not provide a benchmark or mitigation method for LLM-agent traces. Second, broad agent-safety benchmarks [Zhang et al., 2024, Vijayvargiya et al., 2025, Li et al., 2026c] evaluate important risk categories, but do not isolate the ISR-safe composition gap that defines CER. Third, conformal shielding [Scarbro et al., 2025] provides runtime safety under perception uncertainty, while our shield calibrates multi-step trace-risk amplification in tool-using LLM agents. Fourth, proactive runtime monitors [Wang et al., 2025, Qiu et al., 2025] anticipate unsafe behavior, but do not combine CER-specific risk decomposition, long-horizon stress benchmarking, and task-preserving suffix substitution. This work bridges these lines by formalizing CER, constructing CER-BENCH, and providing a conformal runtime shield for calibrated trace-level intervention.

NeurIPS Paper Checklist

1. **Claims**

   Question: Do the main claims made in the abstract and introduction accurately reflect the paper's contributions and scope?

   Answer: [Yes]

   Justification: The abstract and introduction state four contributions: CER formalization and non-detectability analysis, CER-BENCH, RISKSHIELD, and empirical evaluation across current LLM agents. These claims are supported by the problem definition, benchmark construction, method section, and experiments.

2. **Limitations**

   Question: Does the paper discuss the limitations of the work performed by the authors?

   Answer: [Yes]

   Justification: Appendix D.6 discusses benchmark coverage, calibration exchangeability, scale-specific distribution shift, cross-benchmark transfer without conformal coverage, and the need for larger deployment studies.

3. **Theory assumptions and proofs**

   Question: For each theoretical result, does the paper provide the full set of assumptions and a complete proof?

   Answer: [Yes]

   Justification: The non-detectability theorem states the observation-collision condition and deterministic-monitor assumption in Section 2, with proof in Appendix A.1. The conformal score-coverage argument and task-preservation bound state their assumptions in Appendices A.2 and A.3.

4. **Experimental result reproducibility**

   Question: Does the paper fully disclose all the information needed to reproduce the main experimental results of the paper to the extent that it affects the main claims and/or conclusions of the paper?

   Answer: [Yes]

   Justification: Section 4.1 specifies the benchmark tiers, model set, baselines, metrics, temperature setting, repeated-run protocol, calibration/test split, and confidence-interval procedures. Appendices G.1, B.1, and B.2 provide task construction, metric formulas, baseline definitions, and prompt protocols.

5. **Open access to data and code**

   Question: Does the paper provide open access to the data and code, with sufficient instructions to faithfully reproduce the main experimental results?

   Answer: [No]

   Justification: The code and benchmark are not publicly released with this version. The paper and appendices describe the benchmark construction, evaluation protocol, and method.

6. **Experimental setting/details**

   Question: Does the paper specify all the training and test details necessary to understand the results?

   Answer: [Yes]

   Justification: The paper specifies model names and versions, benchmark tiers, prompting and evaluation protocols, calibration/test split, α values, shield operating points, and implementation details in Section 4.1 and the appendices.

7. **Experiment statistical significance**

   Question: Does the paper report error bars suitably and correctly?

   Answer: [Yes]

Justification: The paper reports mean±std over repeated runs where applicable, exact binomial confidence intervals for CG, and percentile bootstrap intervals for TCR. The conformal coverage result is reported separately as a calibrated score-level guarantee under exchangeability.

8. **Experiments compute resources**

   Question: For each experiment, does the paper provide sufficient information on the computer resources needed to reproduce the experiments?

   Answer: [Yes]

   Justification: Experiments use public LLM APIs and local lightweight scoring components. The paper reports online-call overhead and latency/cost analysis in Appendix F.2. Offline CRC calibration is separated from online API/task costs.

9. **Code of ethics**

   Question: Does the research conducted in the paper conform, in every respect, with the NeurIPS Code of Ethics?

   Answer: [Yes]

   Justification: The work is designed to study and reduce agentic safety risks. CER-BENCH uses controlled synthetic tasks and the study is intended for defensive evaluation and mitigation research.

10. **Broader impacts**

    Question: Does the paper discuss both potential positive societal impacts and negative societal impacts of the work?

    Answer: [Yes]

    Justification: Appendix D.6 discusses the positive impact of trace-level safety evaluation and runtime governance for agentic LLMs. It also discusses potential misuse risks from exposing compositional risk patterns, along with safeguards such as synthetic tasks, abstraction of operational details, defensive framing, and the need for deployment-specific calibration.

11. **Safeguards**

    Question: Does the paper describe safeguards that have been put in place for responsible disclosure of data with personal or offensive content?

    Answer: [N/A]

    Justification: CER-BENCH uses synthetic tasks and does not include real user data, private personal information, or real-world sensitive records.

12. **Licenses for existing assets**

    Question: Are the creators or original owners of assets used in the paper properly credited and are the license terms respected?

    Answer: [Yes]

    Justification: Existing models, benchmarks, and safety tools are cited where used. Public APIs and released models are accessed through their official interfaces or documented releases.

13. **New assets**

    Question: Are new assets introduced in the paper well documented and is the documentation provided alongside the assets?

    Answer: [No]

    Justification: No public asset release accompanies this version. Benchmark construction and evaluation details are described in the paper and appendices.

14. **Crowdsourcing and research with human subjects**

    Question: For crowdsourcing experiments and research with human subjects, does the paper include the full text of instructions given to participants and screenshots, if applicable?

    Answer: [N/A]

Justification: This work does not involve crowdsourcing or human subjects research.

15. **Institutional review board (IRB) approvals or equivalent for research with human subjects**

    Question: Does the paper describe potential risks incurred by study participants, whether compensation was provided, and whether informed consent was obtained?

    Answer: [N/A]

    Justification: No human subjects are involved in this research.

16. **Declaration of LLM usage**

    Question: Does the paper describe the usage of LLMs if it is an important, original, or non-standard component of the core methods in this research? Note that if the LLM is used only for writing, editing, or formatting purposes and does not impact the core methodology, scientific rigor, or originality of the research, declaration is not required.

    Answer: [Yes]

    Justification: LLMs are used in benchmark construction, automated safety assessment, agent evaluation, and runtime shielding. Section 4.1 identifies the evaluated models and protocols; Appendices G.1, G.1.4, and E describe construction prompts, machine-judge voting, and the shielding procedure. AI-assisted language editing is disclosed in the acknowledgments.
