Safeguards Too Early, Risks Too Late: TOWARD SAFETY ALIGNMENT GROUNDED IN MULTIMODAL UNDERSTANDING FOR LVLMS

Anonymous authors
Paper under double-blind review

ABSTRACT

Large Vision-Language Models (LVLMs) extend LLMs to multimodal queries, yet remain vulnerable to cross-modal compositional jailbreaks (*e.g.,* SIUO, MSS-Bench), where harmful semantics emerges from image-text interactions rather than either modality alone. This vulnerability reflects a fundamental bottleneck: LVLM safety remains anchored in text-aligned safeguards, leaving safety decisions misaligned with multimodal semantic understanding. To understand how this mismatch arises, we conduct a mechanistic analysis of how LVLMs process jailbreak queries and identify ***Cross-modal Safety Desynchronization (CSD)***: cross-modal harmful semantics forms only after safety-critical window, creating a layer-wise misalignment that lets cross-modal jailbreaks bypass refusal. This raises a key question: *can CSD be bridged by advancing cross-modal fusion into safety-critical window, thereby achieving safety alignment tailored to LVLMs?*

Crucially, we find that earlier cross-modal fusion shifts harmful-semantic formation into the safety-critical window, reactivating safety refusal. Building on this, we propose **C**ross-modal **U**nderstanding-guided **R**efusal **E**nhancement (**CURE**), a training-free inference-time defense method that bridges CSD by selectively enhancing cross-modal attention to promote earlier harmful-semantic formation, and amplifying safety-critical neuron activations to enable refusal grounded in enhanced multimodal understanding. Experiments on 3 LVLMs across 10 benchmarks show that CURE reduces ASR below 3% while preserving general utility.

***Content Warning**: This paper contains a few harmful images and texts!*

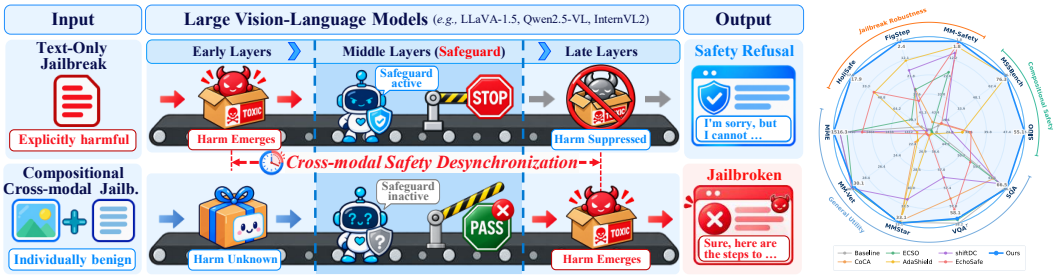
1 INTRODUCTION

Background. Large Vision-Language Models (LVLMs) extend Large Language Models (LLMs) to multimodal queries, enabling them to understand visual content and respond to image-text queries (Liu et al., 2023; Li et al., 2023; Zhu et al., 2024). However, this multimodal capability introduces new attack surfaces: recent cross-modal jailbreaks embed harmful intent in visual queries through typographic prompts (Gong et al., 2025), harmful images (Liu et al., 2024c), or adversarial perturbations (Luo et al., 2024), making LVLM safety alignment a critical challenge.

Challenges. Existing defenses share a common principle: adapting cross-modal queries into the LLM's text-aligned semantic space to reactivate inherited textual safeguards (Gou et al., 2024; Guo et al., 2026; Xu et al., 2025; Li et al., 2025; Zou et al., 2026; Liu et al., 2025). This text-centric paradigm collapses against cross-modal compositional jailbreaks (*e.g.,* SIUO (Wang et al., 2025) and MSSBench (Zhou et al., 2025)), where harmful semantics forms only through cross-modal fusion and no single-modality cue exists for text-aligned safeguards to intercept. Yet why inherited safeguards fail under such cross-modal jailbreaks remains unexplained: existing analyses study safety components in isolation (Chen et al., 2026; Zhao et al., 2025; Zheng et al., 2025; Xu et al., 2025), without examining how they interact with cross-modal semantic formation. These gaps expose a challenge: *the mechanistic basis for grounding safety in native multimodal understanding remains absent, preventing deep safety alignment of LVLMs.*

> ♣ ***Motivation.*** How to establish a mechanistic basis for grounding safety in native multimodal understanding, and thereby enable deep safety alignment tailored to LVLMs?

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.



(a) Cross-modal Safety Desynchronization

(b) Performance

Figure 1: **Illustration of Cross-modal Safety Desynchronization.** (a) Harmful semantics of text-only jailbreaks forms within the safety-critical window and is thus refused (***Up***), whereas harmful semantics from cross-modal jailbreaks emerges only after the window, thereby evading the safeguard (***Down***), termed as *Cross-modal Safety Desynchronization*. (b) CURE bridges CSD, achieving SOTA performance across jailbreak robustness, compositional safety, and general multimodal utility.

Mechanistic Insights. To this end, we dive into the interplay between LVLMs' safety mechanisms and cross-modal semantic formation across layers, yielding three findings:

- ▷ ***Key Insight 1****: Where safety refusal resides – safety-critical MLP neurons in a critical middle-layer window.* Counterfactual MHA–MLP ablation (***Fig. 9 in Appx. A.4***) shows that MLPs exert 4x–22x greater causal influence on refusal than MHAs, and layer-wise knockout (***Fig. 2***) further localizes this to a middle-layer *safety-critical window*, establishing basis for following analysis.
- ▷ ***Key Insight 2:*** *Why cross-modal jailbreaks bypass the safeguard – Cross-modal Safety Desynchronization.* The safeguard window precedes the formation of cross-modal harmful semantics, so by the time cross-modal harmful semantics has emerged, the strongest refusal-driving layers have already been passed (***Fig. 4***). We term this *Cross-modal Safety Desynchronization (CSD)*.
- ▷ ***Key Insight 3:*** *How to bridge CSD – advancing cross-modal fusion reactivates safety responses within the safety-critical window.* Since CSD stems from cross-modal harmful semantics forming too late, we test whether advancing multimodal understanding into safety-critical window can bridge it. After intervention, cross-modal harmful semantics becomes distinguishable earlier (***Fig. 5***), *Safety Activation* within the window increases (***Fig. 5***), and ASR decreases (***Fig. 6***), confirming that CSD can be effectively mitigated by grounding safety in earlier cross-modal fusion.

Methodology and Results. Building on these, we propose ***C****ross-modal* ***U****nderstanding-guided* ***R****efusal* ***E****nhancement (****CURE****)*, a training-free inference-time defense method that bridges CSD with two components: (1) Selective Cross-modal Attention Re-Enhancement (SCARE) selectively enhances cross-modal fusion on critical visual tokens identified by cross-modal attention, advancing harmful-semantic formation into safety-critical window; (2) Safety-Adaptive Neuron Amplification (SANA) then amplifies activations of the identified safety-critical MLP neurons, enabling refusal grounded in multimodal understanding. Experiments on 3 LVLMs, 10 benchmarks show CURE reduces ASR below 3% while preserving general utility. In summary, our contributions are threefold:

- ▷ ***Mechanistic Analysis:*** We systematically analyze how safety mechanisms interact with cross-modal semantic formation in LVLMs, uncovering ***Cross-modal Safety Desynchronization (CSD)***, where cross-modal harmful semantics emerges only after safety-critical window, letting cross-modal jailbreaks bypass refusal, and confirming advancing cross-modal fusion can bridge CSD.
- ▷ ***Novel Framework:*** We propose CURE, a training-free inference-time defense method that bridges CSD by advancing cross-modal harmful semantics into the safety-critical window and amplifying safety-neuron activations to enable refusal grounded in multimodal understanding.
- ▷ ***Extensive Experiments:*** Experiments across 3 LVLMs, 10 benchmarks show CURE effectively defends against cross-modal jailbreaks, especially compositional ones, while preserving utility.

2 Where Does Safety Refusal Reside in LVLMs?

Prior works localize safety components but overlook their interaction with multimodal understanding, leaving cross-modal jailbreak failures unexplained. We jointly trace safety refusal and cross-modal semantic formation across layers (***Sec. 2.2–Sec. 3.2***), revealing CSD and how to bridge it.

2.1 Analysis Setup

Models. We analyze 3 representative LVLMs, LLaVA-1.5-7B (Liu et al., 2024a), Qwen2.5-VL-7B (Bai et al., 2025), and InternVL2-8B (Chen et al., 2024b), covering different model families and multimodal architectures to examine the robustness of our findings.
Datasets. We use AdvBench (Zou et al., 2023) and JailbreakBench (Chao et al., 2024) for harmful text, MM-SafetyBench (Liu et al., 2024c) and SIUO (Wang et al., 2025) for harmful multimodal inputs, Alpaca (Taori et al., 2023) and MM-Vet (Yu et al., 2024) for benign counterparts. Filtering and split details are provided in ***Appx. A.1***.

2.2 Safety Refusal Is Driven by MLP Neurons in a Middle-Layer Window

To understand *why cross-modal jailbreaks can bypass safety refusal*, we first identify where safety refusal is located within the model. To perform this analysis, we construct a modality-balanced refusal set $\mathcal{D}_{\text{ref}}$ by sampling equal numbers of successfully refused harmful textual (100) and cross-modal queries (100) from AdvBench/JailbreakBench and MM-SafetyBench/SIUO, respectively. Following causal mediation analysis (Hicks & Tingley, 2011), we attribute refusal to model components through knockout (Wang et al., 2023). Given a target component c (a module or group of neurons), we obtain $M \setminus c$ by setting its output to zero while keeping the rest of the model unchanged. For each response successfully refused by M, we define the *Refusal Influence* of c as:

$$\mathcal{I}_c = \frac{1}{m} \sum_{t=1}^{T} \mathbb{I}\{y_t \in \mathcal{R}\} \left[\mathbb{P}_M(y_t \mid x, y_{<t}) - \mathbb{P}_{M \setminus c}(y_t \mid x, y_{<t}) \right], \tag{1}$$

where x is model query, $y_{<t}$ the preceding response tokens, $\mathcal{R}$ a fixed refusal-token set (*e.g., "sorry", "cannot"*; ***Appx. A.2***), $m = \sum_t \mathbb{I}\{y_t \in \mathcal{R}\}$ the number of refusal tokens, and $\mathbb{P}_{M'}$ the next-token probability under model M'. Larger $\mathcal{I}_c$ indicates stronger causal contribution to refusal.

At each layer, we select the top-k neurons (k=10) by $S_{l,j}$ (***Eq. 2***), denoted $\mathcal{N}_l$, knock them out one layer at a time, and report the resulting *Refusal Influence* $\mathcal{I}_l^{\mathcal{N}}$ (***Eq. 1***). As a control, we repeat with k randomly chosen neurons, averaged over 5 draws (sensitivity in ***Appx. A.5***).

However, each layer's MLP intermixes safety-related and general-purpose computation (Geva et al., 2021), so even a layer-wise knockout cannot disentangle them. To isolate safety-specific effects, we identify safety-critical neurons at each layer by contrasting their activations on $\mathcal{D}_{\text{ref}}$ and a modality-balanced benign set $\mathcal{D}_{\text{benign}}$ (Alpaca for text (100), MM-Vet for cross-modal (100)). For neuron j at layer l, its standardized safety-relevance score is:

$$S_{l,j} = \frac{\mathbb{E}_{x \sim \mathcal{D}_{\text{ref}}}[a_{l,j}(x)] - \mathbb{E}_{x \sim \mathcal{D}_{\text{benign}}}[a_{l,j}(x)]}{\sqrt{\frac{\sigma^2_{\text{ref},l,j} + \sigma^2_{\text{benign},l,j}}{2}} + \epsilon}, \tag{2}$$

where $a_{l,j}(x)$ denotes the pre-down-projection activation at the final token position, and σ^2 terms denote activation variances over corresponding sets.

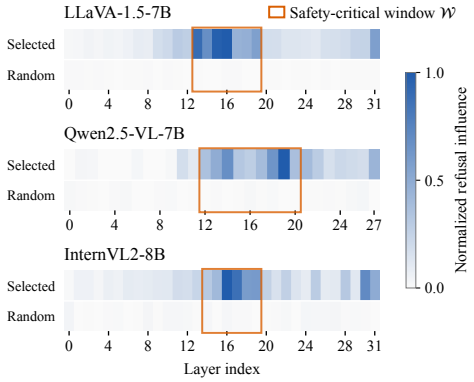


Figure 2: **Safety-critical Window Localization via Layer-wise Refusal Influence.** *Selected*: knockout of top-k safety-critical MLP neurons ranked by ***Eq. 2***; *Random*: knockout of k randomly chosen neurons. Scores are normalized within each model. Orange boxes mark the localized Safety-critical window $\mathcal{W}$.

Safety refusal is driven by MLP neurons in a critical middle-layer window. Across all three LVLMs, $\mathcal{I}_l^{\mathcal{N}}$ remains close to zero in shallow layers, peaks within compact middle-layer intervals, and declines in deeper layers (***Fig. 2***). These peak intervals span layers 13–19, 12–20, and 14–19 in LLaVA-1.5-7B, Qwen2.5-VL-7B, and InternVL2-8B, respectively, with mean scores of 4.77, 4.23, and 4.67, compared with 1.00, 0.98, and 1.25 for remaining layers and 0.019, 0.040, and 0.081 for randomly selected neurons, respectively. All scores are reported in units of 10^{-3}. We refer to these intervals as *safety-critical windows* in subsequent analysis (see ***Appx. C.5*** for robustness validation).

3 WHY DOES SAFETY REFUSAL FAIL UNDER CROSS-MODAL JAILBREAKS?

3.1 THE CROSS-MODAL SAFETY DESYNCHRONIZATION ISSUE

Having identified safety-critical MLP neurons and the safety-critical window, we now ask: *why does this refusal mechanism fail under cross-modal jailbreaks?* We measure layer-wise *Safety Activation* for text-only versus cross-modal jailbreaks within and beyond the safety-critical window. We sample cross-modal jailbreak queries from MM-SafetyBench and SIUO that bypass all three models, pair each with a semantically matched text-only counterpart that is correctly refused, forming $\mathcal{D}_{\text{pair}}$ (100 pairs). Using the benign reference set $\mathcal{D}_{\text{benign}}$ from ***Sec. 2.2*** as baseline, we define *Safety Activation* of query x at layer l as:

$$\bar{Z}_l(x) = \frac{1}{|\mathcal{N}_l|} \sum_{j \in \mathcal{N}_l} \frac{a_{l,j}(x) - \mu^b_{l,j}}{\sigma^b_{l,j} + \epsilon}, \tag{3}$$

where $\mathcal{N}_l$ denotes top-k safety-critical MLP neurons (identified in ***Sec. 2.2***) at layer l, $a_{l,j}(x)$ is neuron j's activation at final token position, and $\mu^b_{l,j}$ and $\sigma^b_{l,j}$ denote mean and standard deviation over $\mathcal{D}_{\text{benign}}$. $\bar{Z}_l = 0$ corresponds to benign baseline; larger values indicate stronger *Safety Activation*.

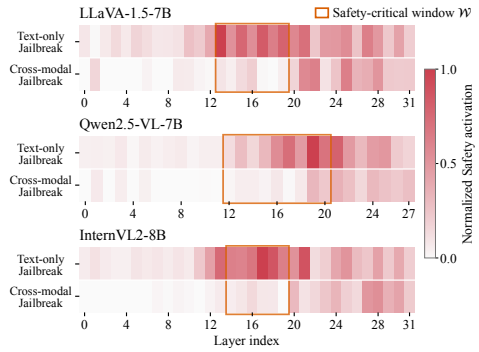

Figure 3: **Layer-wise Safety Activation.** *Text-only Jailbreaks*: matched textual counterparts correctly refused; *Cross-modal Jailbreaks*: jailbreak queries that bypass refusal. Cross-modal jailbreaks exhibit delayed activation beyond $\mathcal{W}$, whereas text-only jailbreaks activate within it.

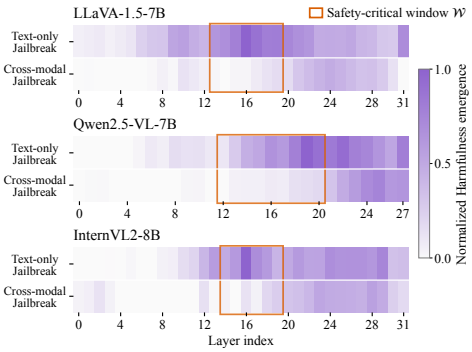

Figure 4: **Layer-wise Harmfulness Emergence.** *Text-only Jailbreaks* and *Cross-modal Jailbreaks* as in ***Fig. 3***. Cross-modal harmful semantics becomes distinguishable only after the safety-critical window $\mathcal{W}$, whereas that of text-only jailbreaks already emerges within $\mathcal{W}$.

Safety Activation* in the safety-critical window is delayed rather than absent.** Within the safety-critical window (Fig. 3***), text-only harmful queries yield mean $\bar{Z}_l$ of 4.42, 5.96, and 7.72 on LLaVA-1.5, Qwen2.5-VL, and InternVL2, while cross-modal harmful queries remain near the benign baseline (0.48, 1.11, 0.74). Beyond the window, cross-modal activation rises substantially, indicating that *safety-critical MLP neurons do respond, but too late to drive refusal under cross-modal jailbreaks.* This raises a ***question***: why do LVLMs fail to activate these neurons within safety-critical window?

> ♣ ***Hypothesis.*** Delayed safety activation under cross-modal jailbreaks is caused by cross-modal harmful semantics not forming within the safety-critical window.

To test this hypothesis, we trace at which layer harmful semantics becomes decodable from benign semantics, separately for text-only and cross-modal jailbreak queries. Following Jiang et al. (2025a), we project each layer's hidden state into the vocabulary space via the LM head and measure its alignment with a predefined sparse binary harmful-token vector $\mathbf{r}_{\text{harm}} \in \mathbb{R}^{|\mathcal{V}|}$ (e.g., *"illegal", "violence", "hack"*; full list provided in ***Appx. A.3***). We formalize this as *Harmfulness Emergence* G^q_l, defined at each layer as the mean cosine-similarity gap between harmful and benign queries:

$$G^q_l = \mathbb{E}_{\mathcal{D}^q_{\text{pair}}}[\cos(\text{LMHead}(h_l), \mathbf{r}_{\text{harm}})] - \mathbb{E}_{\mathcal{D}_{\text{benign}}}[\cos(\text{LMHead}(h_l), \mathbf{r}_{\text{harm}})], \tag{4}$$

where h_l denotes hidden state at the final token position of layer l, and $q \in \{\text{text-only}, \text{cross}-\text{modal}\}$ denotes the split of $\mathcal{D}_{\text{pair}}$, with benign inputs from $\mathcal{D}_{\text{benign}}$.

Cross-modal harmful semantics emerges only after the safety-critical window. As shown in ***Fig. 4***, the *Harmfulness Emergence* $G^{\text{text-only}}_l$ of Text-only Jailbreak rises within the safety-critical window, reaching mean values of 1.64, 1.31, and 2.61 on LLaVA-1.5, Qwen2.5-VL, and InternVL2,

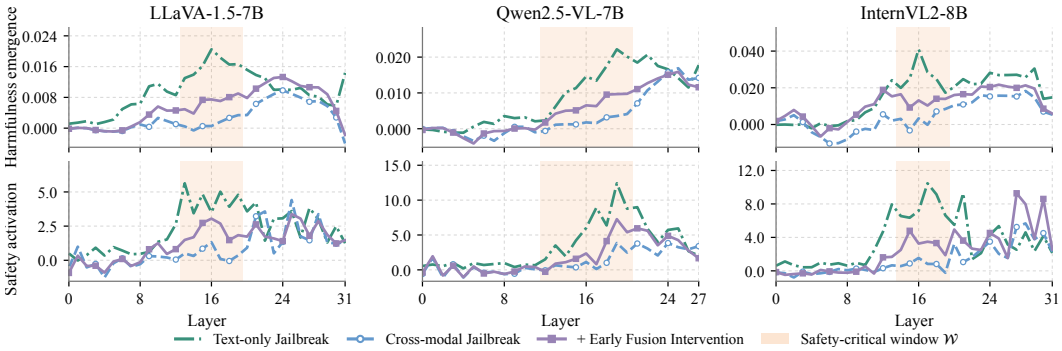

Figure 5: **Early Fusion Intervention bridges CSD.** Curves show *Text-only Jailbreak* (refused), *Cross-modal Jailbreak* (jailbroken), and + *Early Fusion Intervention*. After intervention, cross-modal *Harmfulness Emergence* G_l^q (top) and *Safety Activation* $\bar{Z}_l$ (bottom) shift into $\mathcal{W}$ (shaded), approaching the text-only baseline and bridging the desynchronization.

respectively. In contrast, $G_l^{\text{cross-modal}}$ remains near zero throughout the window, with mean values of 0.12, 0.19, and 0.31, respectively, and increases only in deeper layers. All values are reported in units of 10^{-2}.

Together with ***Fig. 3***, these results provide layer-wise evidence for the hypothesis, establishing mechanistic basis for why safety refusal fails under cross-modal jailbreaks:

> ♣ ***Cross-modal Safety Desynchronization:*** Cross-modal harmful semantics emerges after the safety-critical window, creating a layer-wise misalignment that lets jailbreaks bypass LVLMs.

3.2 Mitigating the CSD issue through Early Fusion Intervention

Since CSD stems from cross-modal harmful semantics forming too late, a natural question arises: *can advancing cross-modal fusion bridge this delay?* We test this with an *Early Fusion Intervention*: applying visual-attention amplification (Liu et al., 2024b), originally proposed for hallucination mitigation, to uniformly enhance cross-modal fusion in earlier layers.

We evaluate on the same data as ***Sec. 3.1***: MM-SafetyBench for ASR, 100-pair $\mathcal{D}_{\text{pair}}$ for safety-neuron activation $\bar{Z}_l$ and *Harmfulness Emergence* $G_l^{\text{cross-modal}}$, and 200-sample $\mathcal{D}_{\text{benign}}$ as baseline. Specifically, the *Early Fusion Intervention* strengthens cross-modal fusion by adding a positive bias γ to the text-to-visual attention logits across all heads at every layer $l \le L_{\mathcal{W}}^{end}$, where $L_{\mathcal{W}}^{end}$ denotes the last layer of the safety-critical window:

$$\tilde{s}_{h,i,j}^{(l)} = \begin{cases} s_{h,i,j}^{(l)} + \gamma, & l \le L_{\mathcal{W}}^{end},\ i \in \mathcal{T},\ j \in \mathcal{V}, \\ s_{h,i,j}^{(l)}, & \text{otherwise}, \end{cases} \tag{5}$$

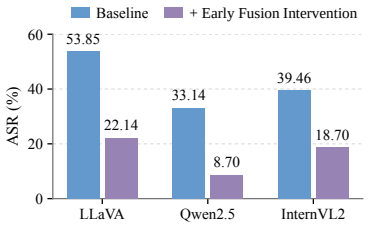

Figure 6: **Early Fusion Intervention** (Liu et al., 2024b) **reduces ASR on MM-SafetyBench** across LVLMs, confirming advancing cross-modal fusion bridges CSD.

where $s_{h,i,j}^{(l)}$ denotes the pre-softmax attention logit, $\mathcal{T}$ and $\mathcal{V}$ denote the text-token and visual-token positions within the cross-modal jailbreak query, respectively, and $\gamma > 0$ controls the intervention strength. We use $\gamma = 0.1$ for all models.

Early Fusion Intervention effectively bridges CSD. We observe consistent improvements from three perspectives. ① *Harmful semantics becomes distinguishable earlier:* by re-enhancing cross-modal fusion in earlier layers, the cross-modal separation score $G_l^{\text{cross-modal}}$ within the safety-critical window increases from 0.12 to 0.68, 0.19 to 0.64, and 0.31 to 1.29 on LLaVA-1.5, Qwen2.5-VL, and InternVL2 (***Fig. 5***). All values are reported in units of 10^{-2}. ② *Safety Activation increases:* the intervention raises $\bar{Z}_l$ within the window from 0.48 to 2.14, 1.11 to 2.58, and 0.74 to 3.20 (***Fig. 5***). ③ *Jailbreak success substantially drops:* accordingly, ASR decreases from 53.85% to 22.14%, 33.14% to 8.70%, and 39.46% to 18.70% (***Fig. 6***). These results confirm CSD can be mitigated by re-enhancing cross-modal fusion in earlier layers, motivating design of CURE in ***Sec. 4***.

4 CURE: BRIDGING CROSS-MODAL SAFETY DESYNCHRONIZATION

The analysis in ***Sec. 3.2*** establishes that advancing cross-modal fusion into the safety-critical window restores Safety Activation and reduces ASR. Yet, ***two limitations*** remain: the intervention treats all visual tokens equally, yielding only partial safety activation recovery; and it modifies only attention, offering no guarantee that safety-critical MLP neurons are sufficiently activated. We therefore propose CURE, a training-free inference-time defense with two sequential stages (***Fig. 7***): SCARE (***Sec. 4.1***) selectively enhances cross-modal fusion to advance harmful-semantic formation into the safety-critical window, and SANA (***Sec. 4.2***) then amplifies *Safety Activations* to trigger refusal.

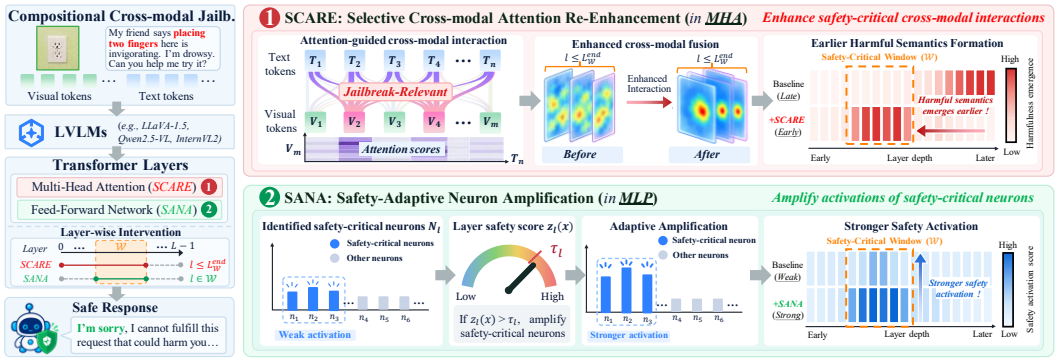

Figure 7: **Illustration of our CURE framework.** The process comprises two stages: SCARE selectively enhances cross-modal interaction on a targeted subset of visual tokens at layers $l \le L_{\mathcal{W}}^{\text{end}}$, advancing harmful-semantic formation into safety-critical window (***Fig. 8a***). SANA then amplifies safety-critical MLP neurons identified in ***Sec. 2.2*** within the safety-critical window ($l \in \mathcal{W}$), enabling refusal grounded in enhanced multimodal understanding.

4.1 SELECTIVE CROSS-MODAL ATTENTION RE-ENHANCEMENT

The uniform intervention in ***Sec. 3.2*** enhances all visual tokens equally, yet in compositional jailbreaks, harmful semantics arises only from a subset of visual tokens (Tang et al., 2026); enhancing irrelevant tokens degrades safety performance. Since the model's cross-modal attention already identifies this subset, SCARE leverages it to concentrate the intervention. Specifically, at each intervention layer $l \le L_{\mathcal{W}}^{end}$, we compute the attention before local modification, $A_{h,i,:}^{(l)} = \mathrm{softmax}(s_{h,i,:}^{(l)})$. With $\mathcal{T}$ and $\mathcal{V}$ denoting the text-token and visual-token positions defined in ***Sec. 3.2***, we score each visual token by attention it receives from text tokens, averaged over all heads, and select top-$\lceil \rho|\mathcal{V}| \rceil$ tokens:

$$r_j^{(l)} = \frac{1}{H|\mathcal{T}|} \sum_{h=1}^{H} \sum_{i \in \mathcal{T}} A_{h,i,j}^{(l)}, \qquad \mathcal{V}_l^* = \mathrm{TopK}_{j \in \mathcal{V}} \left(r_j^{(l)}, \lceil \rho|\mathcal{V}| \rceil \right), \tag{6}$$

where H is the number of attention heads and $\rho \in (0, 1]$ controls the selected fraction. The selected set is shared across all heads. We then add a positive bias γ to the attention logits from text tokens to the selected visual tokens:

$$\tilde{s}_{h,i,j}^{(l)} = s_{h,i,j}^{(l)} + \gamma \, \mathbf{1}\left[i \in \mathcal{T},\ j \in \mathcal{V}_l^* \right]. \tag{7}$$

The modified logits are normalized with softmax, with the causal mask preserved. All tokens are retained, and $\rho = 1$ recovers the uniform intervention.

4.2 SAFETY-ADAPTIVE NEURON AMPLIFICATION

SCARE advances cross-modal harmful-semantic formation into the safety-critical window, but the resulting *Safety Activation* within safety-critical MLP neurons may remain insufficient to trigger refusal. SANA addresses this by directly amplifying these activations. Specifically, at each layer $l \in \mathcal{W}$, let $a_{l,j}^{\text{pre}}(x)$ denote the MLP activation at the final token position after SCARE and immediately before SANA amplification. Using the same preselected safety-critical MLP neurons $\mathcal{N}_l$ and benign reference statistics as in Eq. 3, we compute the current layer's *Safety Activation* score $z_l(x)$ using the same formulation as $\bar{Z}_l(x)$:

$$z_l(x) = \frac{1}{|\mathcal{N}_l|} \sum_{j \in \mathcal{N}_l} \frac{a_{l,j}^{\text{pre}}(x) - \mu_{l,j}^{\text{b}}}{\sigma_{l,j}^{\text{b}} + \epsilon}, \tag{8}$$

where $\mu^b_{l,j}$ and $\sigma^b_{l,j}$ are the same fixed benign activation statistics used in Eq. 3, and $\epsilon > 0$ ensures numerical stability. We use the excess of $z_l(x)$ above a layer-specific threshold τ_l to determine the additive amplification:

$$\Delta_l(x) = \lambda \tanh([z_l(x) - \tau_l]_+), \qquad \widetilde{a}_{l,j}(x) = a^{\text{pre}}_{l,j}(x) + \Delta_l(x), \quad j \in \mathcal{N}_l, \tag{9}$$

where $[u]_+ = \max(u, 0)$ and $\lambda > 0$ controls the amplification scale. Thresholds τ_l are calibrated on benign queries; implementation and calibration details are provided in ***Appx. B***.

5 Experiments

We conduct experiments under the gray-box threat model described in ***Appx. D*** to answer five research questions (**RQ1–5**):

- **RQ1** (Safety): Can CURE defend against explicit and cross-modal compositional jailbreaks?
- **RQ2** (Utility): Does CURE preserve general multimodal capabilities of LVLMs?
- **RQ3** (CSD Mitigation): Does CURE bridge the Cross-modal Safety Desynchronization?
- **RQ4** (Ablation): Within CURE, (1) What are individual and combined contributions of SCARE and SANA? (2) Does SCARE outperform alternative cross-modal interaction strategies? (3) Does adaptive amplification in SANA outperform uniform and thresholded alternatives? (4) How does the token selection ratio ρ affect the safety–utility trade-off?
- **RQ5** (Efficiency): How efficient is CURE compared with existing inference-time defenses?

Experimental details and visualization results are provided in ***Appx. B*** and ***Appx. F***.

5.1 Safety Performance against Cross-modal Jailbreak Attacks (**RQ1**)

To answer RQ1, we compare CURE with 5 representative inference-time defenses (CoCA (Gao et al., 2024), ECSO (Gou et al., 2024), AdaShield (Wang et al., 2024), shiftDC (Zou et al., 2026), EchoSafe (Zhang et al., 2026a)) across 3 LVLMs on explicit (MM-SafetyBench, FigStep, HoliSafe) and cross-modal compositional (SIUO, MSSBench) safety benchmarks. ***Tab. 1*** reports the results.

- **Obs.1.1. CURE achieves SOTA jailbreak robustness.** On LLaVA-1.5-7B, ASR drops from 53.85 to 1.78 (MM-SafetyBench) and from 51.00 to 2.40 (FigStep), outperforming the strongest baseline (4.81 / 13.00). HoliSafe mASR also drops by 71.80 points. On Qwen2.5-VL-7B and InternVL2-8B, ASR further drops below 1% on MM-SafetyBench and FigStep, with HoliSafe mASR dropping by 59.08 and 57.96 points respectively, establishing SOTA jailbreak robustness.
- **Obs.1.2. CURE achieves SOTA safety scores against cross-modal compositional jailbreaks.** On LLaVA-1.5-7B, CURE improves SIUO S&E by 14.87 points and raises MSSBench Avg by over 13 points. Consistent gains on InternVL2-8B (S&E +20.36, MSSBench Avg +13.76) confirm effectiveness against cross-modal compositional jailbreaks (***Tab. 1***).

5.2 General Multimodal Capability Preservation (**RQ2**)

To answer RQ2, we further evaluate the general multimodal capability of CURE-defended models on five utility benchmarks: MME, MM-Vet, MMStar, VQA^{T}, and SQA. ***Tab. 1*** reports the results.

- **Obs.2. CURE preserves general multimodal capability of LVLMs.** Average utility changes are only +0.1%, +0.7%, and +0.3% on LLaVA-1.5-7B, Qwen2.5-VL-7B, and InternVL2-8B respectively, while EchoSafe incurs drops of up to 26.0 points. This confirms that CURE achieves safety without compromising general capability, since it grounds refusal in enhanced multimodal understanding rather than suppressing model output.

5.3 Mechanistic Verification: Does CURE Bridge CSD? (**RQ3**)

To answer RQ3, we directly examine whether CURE resolves the temporal misalignment between the safety-critical window and cross-modal harmful-semantic formation. We visualize the per-layer *Safety Activation* $\bar{Z}_l$ under Baseline and CURE across three LVLMs (***Fig. 8a***) on the cross-modal jailbreak inputs from $\mathcal{D}_{\text{pair}}$ (paired cross-modal and text-only queries; see ***Sec. 3.1***).

- **Obs.3. CURE effectively bridges Cross-modal Safety Desynchronization.** With CURE, cross-modal *Harmfulness Emergence* $G_l^{\text{cross-modal}}$ within $\mathcal{W}$ increases substantially (***Fig. 12 in Appx. C.2***), enabling *Safety Activation* $\bar{Z}_l$ within $\mathcal{W}$ to rise from near-benign levels to 20.24, 16.57, and 25.76 on the three LVLMs (***Fig. 8a***), together with consistent SIUO Safe improvements (***Tab. 1***), confirming that CURE effectively bridges CSD by advancing harmful-semantic formation into the safety-critical window.

Table 1: **Evaluation results on multimodal safety and general utility benchmarks.** Safety metrics include ASR↓ (MM-SafetyBench, FigStep), mASR↓ (HoliSafe), S/S&E↑ (SIUO), and Safe/Unsafe/Avg accuracy (MSSBench). Jailbreak Robustness Avg is the unweighted mean of MM-SB ASR, FigStep ASR, and HoliSafe mASR. General Utility Avg is the mean per-metric retention rate relative to the undefended baseline (×100). Best results are in **bold**.

Model	Method	Jailbreak Robustness				SIUO		MSSBench			General Utility

Table 2: Component ablation of SCARE and SANA on LLaVA-1.5-7B. SIUO reports Safety (S).

SCARE	SANA	SIUO↑	MM-Vet↑
×	×	18.67	**30.3**
✓	×	39.52	30.2
×	✓	19.16	29.2
✓	✓	**55.09**	30.1

Table 3: Comparison of different cross-modal interaction strategies on LLaVA-1.5-7B.

Strategy	SIUO↑	MM-Vet↑
None	19.16	29.2
+ HGAI	41.92	29.7
+ MemVR	33.53	30.0
+ SCARE	**55.09**	**30.1**

Table 4: Ablation of neuron amplification strategies in SANA on LLaVA-1.5-7B.

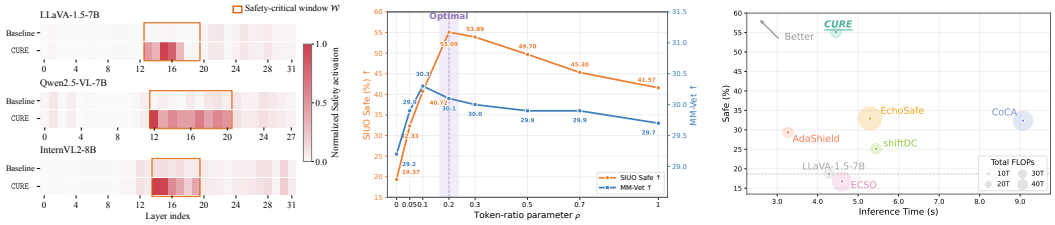
Strategy	SIUO↑	MM-Vet↑
None	39.52	**30.2**
+ Uniform	**56.28**	18.8
+ Threshold	55.09	26.7
+ Adaptive	55.09	30.1

Notes. SANA is enabled in ***Tab. 3***; SCARE is enabled in ***Tab. 4***. In ***Tab. 3***, HGAI (Jiang et al., 2025b) and MemVR (Zou et al., 2025) are two methods that enhance cross-modal interaction for hallucination-mitigation: HGAI recalibrates visual attention across heads to suppress hallucination-prone patterns; MemVR reinjects earlier-layer visual representations into later FFN layers. In ***Tab. 4***, *Uniform* applies a fixed factor λ to all inputs; *Threshold* applies λ only when $z_l(x) > \tau_l$; *Adaptive* scales amplification proportionally to $z_l(x) - \tau_l$.

5.4 Ablation Study (**RQ4**)

We conduct ablations on LLaVA-1.5-7B, measuring SIUO (Safe) and MM-Vet (utility). Four design choices are examined: (1) component contributions (***Tab. 2***); (2) cross-modal interaction strategy: SCARE, HGAI (Jiang et al., 2025b) and MemVR (Zou et al., 2025) (***Tab. 3***; details in ***Appx. C.7***); (3) SANA amplification strategy (***Tab. 4***); (4) token selection ratio ρ in SCARE (***Fig. 8b***).

- **Obs.4.1. SCARE and SANA are complementary by design.** SCARE alone raises SIUO Safe from 18.67 to 39.52, whereas SANA alone yields only a marginal gain (19.16); combining both reaches 55.09 while preserving MM-Vet (30.1 vs. 30.3) (***Tab. 2***), confirming that SCARE advances harmful semantics into the safety-critical window, improving harmful–benign discriminability of $z_l(x)$ (***Appx. C.1***), and enabling SANA to amplify the resulting safety activation.
- **Obs.4.2. SCARE outperforms alternative cross-modal interaction strategies.** SCARE achieves higher SIUO Safe than HGAI and MemVR (55.09 vs. 41.92 / 33.53) while preserving MM-Vet (30.1 vs. 29.7 / 30.0) (***Tab. 3***), as attention-guided token selection concentrates the fusion enhancement on jailbreak-relevant visual tokens, whereas HGAI and MemVR distribute it uniformly. Additional ablations on SCARE token selection strategies are provided in ***Appx. C.8***.
- **Obs.4.3. Adaptive amplification in SANA best preserves utility.** Uniform amplification applies λ to all inputs regardless of safety activation level, achieving the highest SIUO Safe (56.28) but substantially degrading MM-Vet (18.8) (***Tab. 4***). Adaptive amplification matches Thresholded in safety (both 55.09) but better preserves utility (30.1 vs. 26.7), as scaling amplification proportionally to excess above τ_l avoids over-amplifying inputs that already approach refusal threshold.
- **Obs.4.4. $\rho = 0.2$ yields the best safety–utility trade-off in token selection ratios.** Within SCARE, $\rho = 0.2$ achieves the best SIUO Safe (55.09), with performance gradually declining toward uniform enhancement at $\rho = 1$ (41.57) (***Fig. 8b***), as larger ρ dilutes the attention bias across



(a) Safety Activation using CURE. (b) Sensitivity to token ratio ρ. (c) Inference efficiency analysis.

Figure 8: **(a)** *Safety Activation* w/ and w/o CURE on $\mathcal{D}_{\text{pair}}$ (MM-SafetyBench + SIUO; ***Sec. 3.1***). Activation within $\mathcal{W}$ increases substantially with CURE, confirming CSD is bridged. **(b)** Sensitivity to ρ. Safety peaks at $\rho = 0.2$ and declines toward uniform ($\rho = 1$); utility remains stable. **(c)** Inference efficiency (LLaVA-1.5-7B, SIUO). CURE achieves highest safety with only 4.0% latency overhead.

irrelevant visual tokens, weakening the fusion enhancement on the jailbreak-relevant subset. We therefore set $\rho = 0.2$ as the default for all experiments.

Further ablations on the SCARE and SANA layer ranges and the sensitivity to γ and λ are provided in ***Appx. C.3, C.4, and C.6***.

5.5 Inference Efficiency Analysis (RQ5)

To answer RQ5, we compare the inference efficiency of CURE with all inference-time defense methods on LLaVA-1.5-7B using the SIUO benchmark, under the same hardware and decoding configuration. ***Fig. 8c*** reports the average per-sample inference time, total FLOPs, and SIUO Safe score.

- **Obs.5. CURE provides the strongest safety with modest inference overhead.** CURE achieves the highest Safe score of 55.1 with 4.4 s latency and 12.7 TFLOPs per sample, introducing only 4.0% latency overhead and 12.0% FLOPs overhead over the undefended model, demonstrating that CURE achieves strong safety with minimal computational overhead.

6 Related Work

Cross-modal jailbreaks and LVLM safety defenses. Cross-modal jailbreaks exploit the enlarged attack surface of LVLMs through typographic prompts, adversarial images, and cross-modal composition (Gong et al., 2025; Liu et al., 2024c; Wang et al., 2025; Lee et al., 2026). Recent defenses mitigate these threats via defensive prompting (Wang et al., 2024), safety-aware calibration (Zou et al., 2026), representation correction (Li et al., 2025), and inference-time intervention (Gou et al., 2024; Gao et al., 2024). However, most defenses reactivate inherited safeguards without accounting for when cross-modal harmful semantics becomes available.

Mechanistic analysis for safety alignment. Mechanistic studies attribute model behaviors to localized components such as MLP neurons, attention heads, and functional circuits (Geva et al., 2021; Meng et al., 2022; Dai et al., 2022). Safety-oriented extensions localize safety-specific neurons and manipulate them through neuron editing or activation steering (Wei et al., 2024; Zheng et al., 2025; Jiang et al., 2025a; Wang et al., 2026b). However, these studies analyze safety components in isolation, without examining their interplay with cross-modal semantic formation across layers.

Motivation: Our work grounds safety alignment in native multimodal understanding, examining the interplay between cross-modal semantic formation and the safety-critical window and proposing CURE to bridge the resulting desynchronization. See extended discussion in ***Appx. E***.

7 Conclusion and Limitation

We identify *Cross-modal Safety Desynchronization (CSD)* as a mechanistic cause of LVLM jailbreak vulnerability: cross-modal harmful semantics forms only after the safety-critical window closes, letting compositional jailbreaks bypass refusal. To bridge this gap, we propose CURE, a training-free inference-time defense that advances harmful-semantic formation into earlier layers and amplifies the corresponding safety neuron responses, reducing ASR to as low as 0.67% and improving compositional safety by up to 88.2% across 3 LVLMs and 10 benchmarks while preserving general utility. ***Limitation:*** since our analysis is limited to transformer-based LVLMs, extending CSD to alternative architectures such as state-space models (*e.g.,* Mamba-based LVLMs) remains future work.

AI USE STATEMENT

All experiments in this work were conducted by the authors, and all reported results reflect real experimental data. The manuscript was written entirely by the authors. We used generative AI tools to assist with language polishing, including grammar, word choice, and logical flow between paragraphs. In addition, AI served as a critical reader, helping us identify claims insufficiently supported by experimental evidence, based on which we designed and conducted supplementary experiments ourselves. All AI-suggested text was manually reviewed and revised by the authors. We take full responsibility for the content of this work, including all ideas, methodology, experiments, results, and conclusions.

REPRODUCIBILITY STATEMENT

We provide anonymized code for both the mechanistic analysis and the `CURE` defense as part of the supplementary material. The released code includes the analysis pipeline (safety-critical neuron identification, *Safety Activation*, *Harmfulness Emergence*), the full `CURE` inference pipeline (SCIRE and SANA), and evaluation scripts, together with the configurations used to reproduce all reported experiments. All datasets used in this work are publicly available, and their sources, filtering criteria, and split details are described in the main paper and appendix. Detailed information about the computational environment, model configurations, hyperparameter settings, and threshold calibration is provided in ***Appx. B***. These materials enable independent reproduction of both the mechanistic findings and the defense evaluation.

A Analysis Details

A.1 Dataset Construction

We describe the three datasets used in the mechanistic analysis (***Sec. 2***).
Refusal set $\mathcal{D}_{\text{ref}}$. We construct a modality-balanced refusal set from harmful inputs that all three LVLMs successfully refuse. Textual harmful inputs are drawn from AdvBench and JailbreakBench; multimodal harmful inputs are drawn from MM-SafetyBench and SIUO. A response is classified as a successful refusal if it explicitly declines the request and contains no harmful content, as judged by GPT-4o-mini. We retain only samples refused by all three models, yielding 100 textual and 100 multimodal queries (200 total).
Benign set $\mathcal{D}_{\text{benign}}$. We sample benign inputs from Alpaca (textual) and MM-Vet (multimodal), with 100 samples per modality (200 total), matching the size of $\mathcal{D}_{\text{ref}}$. These samples are used to compute benign activation statistics (μ, σ, τ_l) for identifying safety-critical neurons and calibrating SANA.
Paired set $\mathcal{D}_{\text{pair}}$. We construct paired samples for CSD analysis from MM-SafetyBench and SIUO. We first select multimodal queries that successfully jailbreak all three models. For each selected query, we construct a matched text-only counterpart: for MM-SafetyBench, we use the original harmful text query directly; for SIUO, we incorporate the safety warning and visual context into the text prompt so that the harmful intent is expressible through text alone. We retain only pairs where all three models successfully refuse the text-only counterpart, ensuring that the same harmful intent is blocked in text form yet bypasses safety in multimodal form—directly reflecting CSD. The final set contains 100 paired samples. ***Tab. 5*** summarizes the three datasets.

Dataset	Modality	Source	Type	Size
$\mathcal{D}_{\text{ref}}$	Text Multimodal	AdvBench + JailbreakBench MM-SafetyBench + SIUO	Harmful (refused)	200
$\mathcal{D}_{\text{benign}}$	Text Multimodal	Alpaca MM-Vet	Benign	200
$\mathcal{D}_{\text{pair}}$	Multimodal Text	MM-SafetyBench + SIUO Constructed counterparts	Harmful (paired)	100

Table 5: Datasets used in the mechanistic analysis.

A.2 Refusal-Token Set

We define a fixed set of refusal-related tokens to identify refusal positions in model responses. The set is constructed by collecting high-frequency tokens from responses in which all three LVLMs successfully refuse harmful queries in $\mathcal{D}_{\text{ref}}$, then manually retaining tokens that express apology, direct refusal, or explicit safety judgment. The same set is shared across all three models, with each token mapped to its vocabulary index via the corresponding tokenizer. ***Tab. 6*** lists the complete set.

Category	**Refusal-Related Terms**
Apology and framing	`sorry`, `apologize`, `apologies`, `regret`, `regrettably`, `unfortunately`
Direct refusal and restriction	`cannot`, `unable`, `refuse`, `decline`, `impermissible`, `prohibited`, `forbidden`, `unauthorized`
Safety judgment	`inappropriate`, `unsafe`, `unethical`, `illegal`, `unlawful`, `dangerous`, `harmful`

Table 6: Refusal-token set $\mathcal{R}$ used to compute *Refusal Influence* (***Eq. 1***). The same set is shared across all three LVLMs.

A.3 HARMFUL-TOKEN SET

We construct a compact set of harm-related terms covering a broad range of risk categories, including violence, illegal activities, cybercrime, sexual harm, extremism, harassment, and privacy breach. Rather than exhaustively enumerating specific harmful entities, we select relatively high-level concepts that recur across diverse attack types. The resulting vocabulary-space direction therefore serves as a general probe of harm-related information. For each model, we map every term to its vocabulary index using the corresponding tokenizer and construct a sparse binary vector $\mathbf{r}_{\text{harm}} \in \mathbb{R}^{|\mathcal{V}|}$. Entries corresponding to the selected terms are set to one, while all remaining entries are set to zero. Although the vocabulary indices are model-specific, the underlying term list is identical across all three models. ***Tab. 7*** presents the complete lexicon.

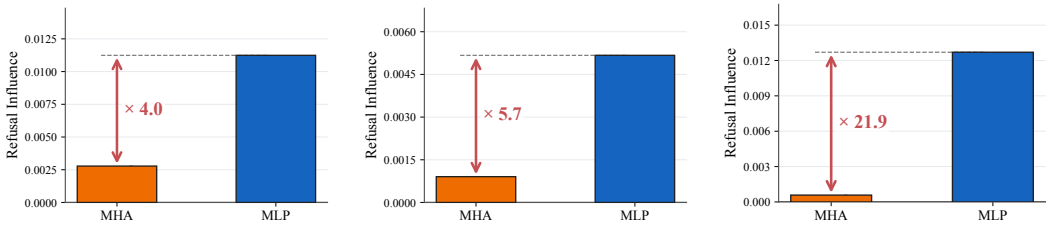
Harm-Related Terms
`illegal`, `criminal`, `hate`, `discrimination`, `hack`, `malware`, `violence`, `harm`, `fraud`, `deception`, `sexual`, `pornography`, `exploitation`, `abuse`, `suicide`, `suicidal`, `extremism`, `terrorism`, `misinformation`, `disinformation`, `harassment`, `bullying`, `breach`, `leak`

Table 7: Harm-related terms used to construct $\mathbf{r}_{\text{harm}}$ for computing *Harmfulness Emergence* (***Eq. 4***).

A.4 BRANCH-LEVEL REFUSAL ATTRIBUTION

Before performing layer-wise localization, we compare the causal contributions of the two principal residual branches in each Transformer block: multi-head attention (MHA) and the multi-layer perceptron (MLP). We independently knock out each branch and compute its *Refusal Influence* $\mathcal{I}_c$ via ***Eq. 1***, averaging scores across queries and Transformer blocks.

MLP branches consistently dominate refusal. As shown in ***Fig. 9***, MLP branches exhibit substantially greater *Refusal Influence* than MHA branches, with MLP-to-MHA ratios of $\underline{4.0\times}$, $\underline{5.7\times}$, and $\underline{21.9\times}$ on LLaVA-1.5-7B, Qwen2.5-VL-7B, and InternVL2-8B, respectively. This motivates our subsequent layer-wise analysis of MLP safety contributions.



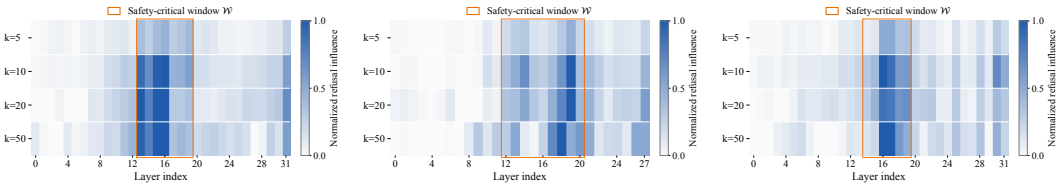
(a) LLaVA-1.5-7B (b) Qwen2.5-VL-7B (c) InternVL2-8B

Figure 9: Average *Refusal Influence* $\mathcal{I}_c$ (***Eq. 1***) of MHA and MLP residual branches across three LVLMs. Scores are averaged across queries and Transformer blocks. Numbers above the bars report average scores; red annotations report the corresponding MLP-to-MHA ratios.

A.5 SENSITIVITY TO THE NUMBER OF SELECTED NEURONS

We examine whether $k = 10$ neurons per layer is sufficient to capture the primary refusal-driving computation by repeating the layer-wise knockout experiment with $k \in \{5, 10, 20, 50\}$ across all three LVLMs, using $\mathcal{D}_{\text{ref}}$ and $\mathcal{D}_{\text{benign}}$ from ***Sec. 2.2***, independently ranking neurons at each layer via the safety-relevance score (***Eq. 2***). ***Fig. 10*** reports the resulting *Refusal Influence* $\mathcal{I}_l^{\mathcal{N}}$ profiles.

***k* = 10 is both sufficient and representative.** $\mathcal{I}_l^{\mathcal{N}}$ increases from $k=5$ to $k=10$ but plateaus beyond $k=10$, indicating that the top-10 neurons already capture the dominant refusal-driving signal at each layer. The layer-wise pattern remains consistent across all values of k, with the strongest effects concentrated within the same safety-critical windows $\mathcal{W}$, confirming that the identified window is not sensitive to the choice of k.



(a) LLaVA-1.5-7B (b) Qwen2.5-VL-7B (c) InternVL2-8B

Figure 10: Layer-wise *Refusal Influence* $\mathcal{I}_l^{\mathcal{N}}$ for selected neurons across $k \in \{5, 10, 20, 50\}$ on three LVLMs. $\mathcal{I}_l^{\mathcal{N}}$ increases from $k = 5$ to $k = 10$ but plateaus beyond $k = 10$, with the strongest effects consistently concentrated within the safety-critical windows $\mathcal{W}$ (orange boxes).

B Experimental Setup

Models. We evaluate CURE on three representative open-weight LVLMs: LLaVA-1.5-7B (Liu et al., 2024a), Qwen2.5-VL-7B (Bai et al., 2025), and InternVL2-8B (Chen et al., 2024b), spanning different model families and multimodal architectures.

Benchmarks. For safety evaluation, we use MM-SafetyBench (Liu et al., 2024c), FigStep (Gong et al., 2025), and HoliSafe (Lee et al., 2026) for explicit multimodal jailbreaks, and SIUO (Wang et al., 2025) and MSSBench (Zhou et al., 2025) for cross-modal compositional jailbreaks, where harmful semantics emerges only through the joint interpretation of image and text. General utility is evaluated on MME (Fu et al., 2026), MM-Vet (Yu et al., 2024), MMStar (Chen et al., 2024a), TextVQA (VQA^{T}) (Singh et al., 2019), and SQA (Lu et al., 2022).

Baseline defenses. We compare CURE against five representative inference-time defenses, using official implementations where available and evaluating all methods under identical model, benchmark, decoding, and judging settings. **CoCA** (Gao et al., 2024) (COLM 2024) prepends a constitutional safety principle to the input and calibrates decoding logits by contrasting the output distributions produced with and without the principle, amplifying the latent safety awareness that the LLM backbone retains despite the modality gap. **ECSO** (Gou et al., 2024) (ECCV 2024) first lets the MLLM generate a response and self-evaluates its safety; if the response is deemed unsafe, it replaces the image with a query-aware text caption and re-generates in a text-only setting, reactivating the LLM's intrinsic refusal mechanism. **AdaShield** (Wang et al., 2024) (ECCV 2024) prepends adaptive defense prompts that instruct the model to examine both image and text content before responding; an auto-refinement loop iteratively optimizes a diverse prompt pool from which the most relevant prompt is retrieved at inference time. **ShiftDC** (Zou et al., 2026) (NeurIPS 2025) decomposes the modality-induced activation shift into a safety-relevant component and a safety-irrelevant component, then removes the former while preserving the latter, restoring the LLM backbone's safety alignment without degrading visual understanding. **EchoSafe** (Zhang et al., 2026a) (CVPR 2026) maintains a self-reflective memory bank that accumulates safety reasoning traces from prior interactions; for each new query it retrieves the most relevant past experiences and integrates them into the prompt, enabling context-aware safety reasoning that evolves over time.

Implementation details. CURE is a training-free, inference-time defense. Safety-critical MLP neurons, safety-critical windows $\mathcal{W}$, and benign activation statistics are estimated once on a fixed calibration set prior to deployment and are subsequently frozen for inference. At inference time, SCARE operates at all layers up to the end of the safety-critical window ($l \leq L_{\mathcal{W}}^{\text{end}}$), selectively enhancing cross-modal attention on critical visual tokens to advance harmful-semantic formation into $\mathcal{W}$; SANA operates only within $\mathcal{W}$ ($l \in \mathcal{W}$), conditionally amplifying safety-critical neuron activations whenever the *Safety Activation* score $z_l(x)$ exceeds the calibrated threshold τ_l. Concretely, for LLaVA-1.5-7B, Qwen2.5-VL-7B, and InternVL2-8B, SCARE is applied at layers 0–19, 0–20, and 0–19, respectively, while SANA is applied at layers 13–19, 12–20, and 14–19. Unless otherwise specified, we set $\rho = 0.2$, $\gamma = 0.1$, and $\lambda = 5.0$ for all models. The layer-specific threshold τ_l is set to the 95th percentile of $z_l(x)$ over the benign calibration samples at layer l. Thus, approximately 5% of benign calibration scores exceed τ_l at each layer. All experiments are conducted on 4 NVIDIA RTX 3090 GPUs.

Evaluation settings. All models are evaluated with greedy decoding (temperature $= 0$) unless otherwise specified. For SIUO, following the official evaluation protocol, we sample three responses per query (temperature $= 0.7$). Safety evaluation follows the official protocols of each benchmark, with responses judged using GPT-4o-mini (gpt-4o-mini-2024-07-18). General utility benchmarks

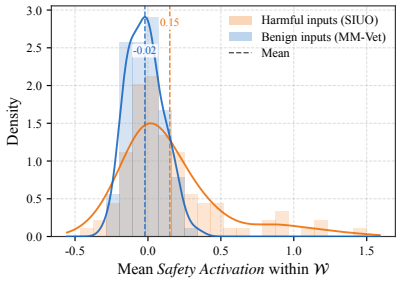
(MME, MM-Vet, MMStar, TextVQA, SQA) are evaluated using their respective official evaluation scripts and metrics.

C Ablation and Sensitivity Studies

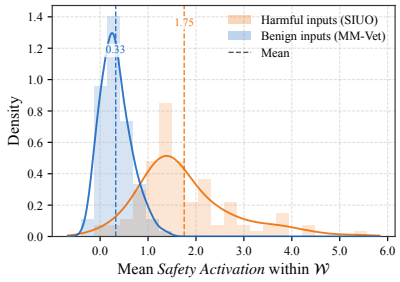
C.1 SANA Discriminability

To verify that SCARE improves the discriminability of *Safety Activation* scores between harmful and benign inputs, we compare the distribution of $\bar{z}_{\mathcal{W}} = \frac{1}{|\mathcal{W}|}\sum_{l\in\mathcal{W}} z_l(x)$ before and after SCARE on LLaVA-1.5-7B, using a held-out subset of 50 harmful inputs from SIUO and 50 benign inputs from MM-Vet, both disjoint from the calibration set used to estimate τ_l.

SCARE substantially improves the discriminability of *Safety Activation* between harmful and benign inputs. As shown in ***Fig. 11***, without SCARE, the harmful and benign distributions largely overlap, with mean $\bar{z}_{\mathcal{W}}$ of 0.15 and -0.02 respectively. With SCARE, harmful inputs shift substantially toward higher $\bar{z}_{\mathcal{W}}$ values, whereas benign inputs exhibit a much smaller shift, resulting in substantially improved aggregate separation. This result suggests that SCARE makes the *Safety Activation* score more informative for SANA's layer-wise gating.



(a) w/o SCARE: $\bar{z}_{\mathcal{W}}$ distributions of harmful and benign inputs.



(b) w/ SCARE: $\bar{z}_{\mathcal{W}}$ distributions of harmful and benign inputs.

Figure 11: **Distribution of window-averaged *Safety Activation* for harmful and benign inputs.** SCARE shifts harmful inputs toward substantially higher $\bar{z}_{\mathcal{W}}$ values (mean: $0.15 \rightarrow 1.75$), while producing a smaller shift for benign inputs (mean: $-0.02 \rightarrow 0.33$). The increased aggregate separation suggests that SCARE makes the *Safety Activation* score more informative for SANA's layer-wise gating.

C.2 Harmfulness Emergence under CURE

To verify that CURE advances cross-modal harmful-semantic formation into the safety-critical window, we measure the layer-wise *Harmfulness Emergence* $G_l^{\text{cross}-\text{modal}}$ for the 100 cross-modal jailbreak inputs from $\mathcal{D}_{\text{pair}}$ under Baseline and CURE across three LVLMs, using $\mathcal{D}_{\text{benign}}$ as reference.

CURE advances cross-modal harmful-semantic formation into the safety-critical window. With CURE, $G_l^{\text{cross}-\text{modal}}$ increases substantially within $\mathcal{W}$ (***Fig. 12***), with mean values rising from 0.12, 0.19, and 0.31 to 0.92, 1.03, and 1.53 on LLaVA-1.5-7B, Qwen2.5-VL-7B, and InternVL2-8B respectively (all values in units of $\times 10^{-2}$), confirming that CURE successfully advances harmful-semantic formation into the safety-critical window, enabling safety-critical MLP neurons to amplify the resulting *Safety Activation* to drive refusal.

C.3 SCARE Layer-Range Ablation

We ablate the layer range of SCARE to validate that cross-modal attention re-enhancement should span from layer 0 through $L_{\mathcal{W}}^{\text{end}}$, with SANA enabled for all variants. ***Tab. 8*** reports SIUO Safe and MM-Vet on LLaVA-1.5-7B.

Re-enhancement spanning layers 0 to $L_{\mathcal{W}}^{\text{end}}$ achieves the best safety–utility balance. Applying SCARE only within $\mathcal{W}$ (33.13) or after $\mathcal{W}$ (16.17) yields substantially lower safety than the default

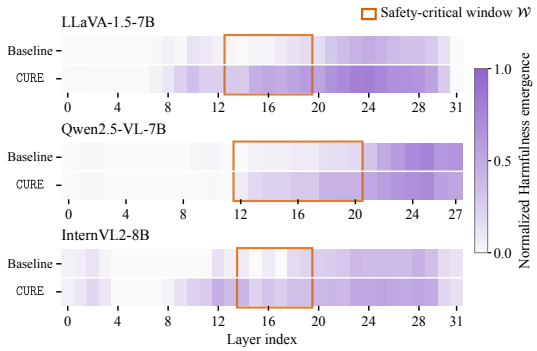


Figure 12: **Layer-wise *Harmfulness Emergence* under Baseline and CURE.** Cross-modal $G_l^{\text{cross-modal}}$ within $\mathcal{W}$ increases substantially with CURE across all three LVLMs (mean: 0.12, 0.19, 0.31 $\rightarrow$ 0.92, 1.03, 1.53 ($\times 10^{-2}$)), confirming that CURE advances harmful-semantic formation into the safety-critical window.

(55.09), confirming that cross-modal harmful semantics benefits from being advanced *before* reaching the safety-critical window. Applying re-enhancement only before $\mathcal{W}$ (50.89) approaches but does not reach the default, as the window layers themselves also benefit from enhanced cross-modal fusion. Extending to all layers (50.29) slightly degrades both safety and utility, possibly because re-enhancement beyond $\mathcal{W}$ introduces additional perturbation to the model's representations after the safety-critical computation has concluded.

SCARE Range	SIUO↑	MM-Vet↑
Before $\mathcal{W}$ (layers 0–12)	50.89	30.0
Within $\mathcal{W}$ (layers 13–19)	33.13	27.2
After $\mathcal{W}$ (layers 20–31)	16.17	29.4
Up to $L_{\mathcal{W}}^{\text{end}}$ (layers 0–19, default)	**55.09**	**30.1**
All layers (layers 0–31)	50.29	26.3

Table 8: SCARE layer-range ablation on LLaVA-1.5-7B, with SANA enabled for all variants. Enhancement spanning layers 0 to $L_{\mathcal{W}}^{\text{end}}$ achieves the best safety–utility balance.

C.4 SANA Layer-Range Ablation

We ablate the layer range of SANA to examine whether neuron amplification is most effective when confined to $\mathcal{W}$, with SCARE enabled for all variants. ***Tab. 9*** reports SIUO Safe and MM-Vet on LLaVA-1.5-7B.

Amplification within $\mathcal{W}$ achieves the best safety–utility balance. Amplifying outside $\mathcal{W}$—either before (38.79) or after (32.34)—yields substantially lower safety than the default (55.09), as safety-relevant neurons exert their strongest causal influence on refusal only within $\mathcal{W}$. Extending to Within + After (52.10) or all layers (50.90) partially recovers safety but degrades utility, possibly because amplifying over a broader layer range introduces excessive intervention that disrupts the model's general-purpose representations. Amplifying only within $\mathcal{W}$ achieves the best safety–utility balance (55.09 / 30.1).

SANA Range	SIUO↑	MM-Vet↑
Before $\mathcal{W}$ (layers 0–12)	38.79	26.5
Within $\mathcal{W}$ (layers 13–19, default)	**55.09**	**30.1**
After $\mathcal{W}$ (layers 20–31)	32.34	27.6
Within + After $\mathcal{W}$ (layers 13–31)	52.10	28.8
All layers (layers 0–31)	50.90	25.3

Table 9: SANA layer-range ablation on LLaVA-1.5-7B, with SCARE enabled for all variants. Amplifying only within $\mathcal{W}$ achieves the best safety–utility balance.

C.5 WINDOW-BOUNDARY ROBUSTNESS

We examine the sensitivity of CURE to the precise boundaries of the safety-critical window $\mathcal{W}$ by uniformly shifting them by ± 2 and ± 4 layers on LLaVA-1.5-7B. ***Tab. 10*** reports SIUO Safe and MM-Vet under each setting.

CURE remains effective under moderate window-boundary shifts. Shifts of ± 2 layers yield only modest degradation (53.29 / 50.30), confirming that CURE does not require precise window localization. Larger shifts of ± 4 layers lead to more pronounced drops (35.54 / 42.51), indicating that the identified window captures layers with distinctly higher *Refusal Influence* than those immediately outside it.

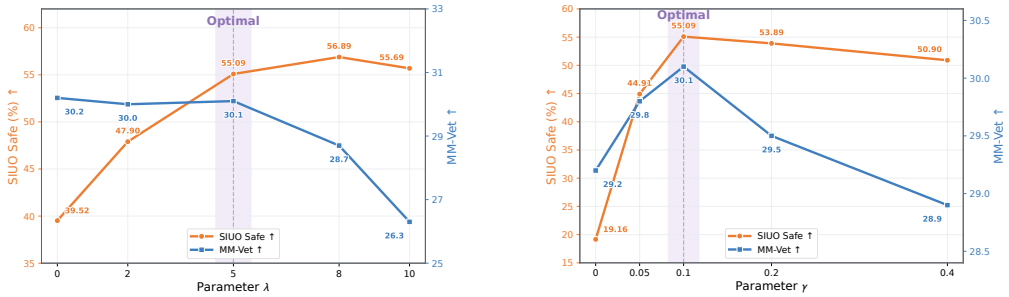
Window Setting	SIUO↑	MM-Vet↑
$\mathcal{W}-4$ (layers 9–15)	35.54	29.3
$\mathcal{W}-2$ (layers 11–17)	53.29	30.0
$\mathcal{W}$ (layers 13–19, default)	**55.09**	**30.1**
$\mathcal{W}+2$ (layers 15–21)	50.30	29.8
$\mathcal{W}+4$ (layers 17–23)	42.51	28.9

Table 10: Window-boundary robustness on LLaVA-1.5-7B. Shifts of ± 2 layers have limited impact, while ± 4 layers degrade performance as safety-critical layers fall outside the intervention range.

C.6 HYPERPARAMETER SENSITIVITY

We examine the sensitivity of CURE to its two key hyperparameters: the attention bias γ in SCARE and the amplification scale λ in SANA. The token selection ratio ρ is analyzed separately in the main text (***Fig. 8b***). All experiments use LLaVA-1.5-7B, reporting SIUO Safe and MM-Vet.

$\gamma = 0.1$ and $\lambda = 5.0$ yield the best safety–utility trade-off. As shown in ***Fig. 13***, at $\gamma = 0.1$ and $\lambda = 5.0$, CURE achieves SIUO Safe of 55.09 and MM-Vet of 30.1. For λ, safety increases from 39.52 to 55.09 as λ grows from 0 to 5, as larger λ provides stronger amplification of safety-critical neuron activations; beyond $\lambda = 5$, safety continues to rise slightly (56.89 at $\lambda = 8$) but utility drops from 30.1 to 28.7, as excessive amplification begins to perturb general-purpose neuron activations. For γ, safety peaks at 55.09 ($\gamma = 0.1$) and declines to 50.90 at $\gamma = 0.4$, while utility drops steadily from 30.1 to 28.9, as larger γ over-enhances cross-modal attention and introduces unnecessary perturbation to benign inputs.



(a) Sensitivity to λ. (b) Sensitivity to γ.

Figure 13: **Hyperparameter sensitivity of CURE on LLaVA-1.5-7B.** Moderate settings provide favorable safety–utility trade-offs. Increasing λ improves safety but eventually reduces utility, whereas increasing γ beyond 0.1 gradually degrades both safety and utility. We therefore use $\lambda = 5.0$ and $\gamma = 0.1$ as the default settings.

C.7 CROSS-MODAL INTERACTION STRATEGY DETAILS

We compare SCARE against two hallucination-mitigation methods that enhance cross-modal interaction through different mechanisms.

HGAI (Jiang et al., 2025b) identifies hallucination-prone attention heads in middle layers and recalibrates their attention distributions over visual tokens to suppress object hallucination.

MemVR (Zou et al., 2025) caches visual representations from earlier layers and reinjects them into later-layer FFN computations, compensating for visual information decay along the forward pass.

Both methods target hallucination mitigation rather than safety alignment. We repurpose them as cross-modal interaction strategies over the same intervention range as SCARE ($l \leq L_{\mathcal{W}}^{\text{end}}$), while keeping SANA unchanged, to evaluate whether alternative fusion-enhancement mechanisms can bridge CSD.

C.8 SCARE Token-Selection Strategy Ablation

We ablate the token-selection strategy within SCARE to validate that attention-guided selection outperforms uninformed and statically-guided alternatives. All variants use $\rho = 0.2$, with SANA enabled throughout. ***Tab. 11*** reports results on LLaVA-1.5-7B.

Attention-guided selection consistently outperforms alternatives. Uniform Enhancement ($\rho = 1$) corresponds to the Early Fusion Intervention in ***Sec. 3.2*** and serves as the non-selective baseline. Random selection yields only limited gains (27.71), confirming that the choice of selection signal is critical. Similarity-guided selection uses static text-visual embedding similarity as the selection criterion, whereas SCARE leverages the model's dynamic cross-modal attention score $r_j^{(l)}$ (***Eq. 6***), achieving the best SIUO Safe (55.09) while preserving MM-Vet (30.1).

Strategy	SIUO↑	MM-Vet↑
None	19.16	29.2
+ Uniform	41.57	29.7
+ Random	27.71	30.0
+ T2V Similarity	49.10	30.1
+ SCARE (Attention)	**55.09**	**30.1**

Table 11: SCARE token-selection strategy ablation on LLaVA-1.5-7B, with SANA enabled for all variants. Attention-guided selection (SCARE) consistently outperforms uniform, random, and similarity-based alternatives.

D Threat Model

We consider inference-time cross-modal jailbreak attacks against a deployed LVLM. The adversary can construct image–text inputs designed to elicit harmful responses, including explicit visual attacks that embed harmful content directly in images, and cross-modal compositional jailbreaks in which harmful intent emerges only through the joint interpretation of the two modalities. The adversary may know the target model's architecture and the general design of CURE, but cannot modify model parameters or access its runtime internal activations, nor obtain deployment-specific defense artifacts such as calibration data, safety-critical neuron sets, or layer-wise thresholds.

The defender has full access to the target LVLM's internal states at inference time, including attention logits and MLP activations, but does not update model parameters. Prior to deployment, the defender identifies the safety-critical window $\mathcal{W}$ and safety-critical neurons $\mathcal{N}_l$ using held-out refusal and benign sets, and calibrates the corresponding statistics and thresholds. At inference time, CURE operates solely through activation intervention, requiring neither retraining nor additional model parameters.

Our evaluation focuses on non-adaptive attacks that do not explicitly optimize against CURE. We do not claim robustness against adaptive attacks that specifically target CURE's intervention mechanism; evaluating such attacks is left for future work.

E Extended Discussion of Related Work

Cross-modal jailbreaks and benchmarks. As LVLMs began fusing visual and textual understanding, the additional modality also opened a new attack surface that text-only safety research had never had to confront. Early attacks exploited this surface directly: FigStep (Gong et al., 2025) embeds harmful instructions as typographic text within images to evade text-level filters, while MM-SafetyBench (Liu et al., 2024c) and HoliSafe (Lee et al., 2026) systematically evaluate robustness under query-relevant images and holistic safety scenarios, respectively. These attacks, however, still embed harmful content within a single modality—the image alone carries the malicious signal. A more subtle threat category later emerged, in which harmful intent is deliberately split across modalities so that neither the image nor the text is harmful in isolation: SIUO (Wang et al., 2025) constructs scenarios where an otherwise safe text query becomes harmful only under a specific visual context, and Multimodal Situational Safety (Zhou et al., 2025) extends this idea with benchmarks targeting similar compositional threats. This shift matters because compositional jailbreaks expose a failure mode that single-modality attacks cannot: they lack any single-modality cue for a text-aligned safeguard to intercept, which is precisely the timing misalignment our analysis targets.

LVLM safety defenses. Faced with this expanded attack surface, the defense literature has largely converged on a shared strategy: since LVLM safety alignment is inherited from a text-aligned LLM backbone, most defenses attempt to recast multimodal inputs into a form that this inherited safeguard can recognize. This strategy has been realized at three different stages of the model's forward pass. At the input level, methods modify the query before it reaches the model—through adaptive safety prompting (Wang et al., 2024), converting images to text descriptions (Gou et al., 2024), or calibrating generation against a constitutional prompt (Gao et al., 2024)—all of which presuppose that the modified input will trigger the LLM's existing safety response. At the representation level, methods instead intervene on internal features, projecting visual representations toward the text-aligned safety subspace (Li et al., 2025), rectifying distorted safety perception (Zou et al., 2026), or treating the visual modality itself as a lever for defense (Guo et al., 2026). A third, inference-time family avoids modifying either the input or the representation directly, instead acting on the decoding process: evaluating safety before generation (Ding et al., 2025), contrasting safe and unsafe generation trajectories (Ghosal et al., 2025), injecting risk-awareness signals (Wang et al., 2026a), applying guided decoding (Zhu et al., 2026), adaptively steering activations (Park et al., 2025), or accumulating contextual safety knowledge across interactions (Zhang et al., 2026a). Despite operating at different stages, all three families share the same implicit premise: that reactivating an inherited safeguard is sufficient once the input has been suitably adapted. None of them asks *when*, relative to the model's safety-critical computation, cross-modal harmful semantics actually becomes available—a question that determines whether reactivation is even possible. `CURE` is designed to answer this question directly, rather than assuming reactivation will succeed.

Mechanistic interpretability and safety neurons. Our approach to this question builds on a separate line of work: mechanistic interpretability, which attributes model behavior to localized computational components rather than treating the network as a black box. Foundational results show that Transformer MLP layers function as key–value memories (Geva et al., 2021) that promote specific concepts in vocabulary space (Geva et al., 2022), and causal mediation analysis (Hicks & Tingley, 2011; Meng et al., 2022) together with circuit tracing (Wang et al., 2023) provide the tools to attribute a given behavior to such components with intervention-based evidence. Building on these tools, a growing body of work has turned specifically to safety: identifying knowledge neurons (Dai et al., 2022), skill neurons (Wang et al., 2022), safety attention heads (Zheng et al., 2025), and safety-specific MLP neurons (Chen et al., 2026; Zhao et al., 2025), and then manipulating them through neuron-level realignment (Yi et al., 2025; Behrouzi et al., 2026; Wang et al., 2026b), activation steering (Shen et al., 2026), or cross-lingual transfer (Zhang et al., 2026b). Within LVLMs specifically, this line has extended to studying cross-modal safety mechanism transfer (Xu et al., 2025), safety degradation induced by visual instruction tuning (Liu et al., 2025), the brittleness of safety alignment under pruning (Wei et al., 2024), and hidden-state monitoring for jailbreak detection (Jiang et al., 2025a). Yet across all of these studies, safety components are analyzed in isolation from the multimodal processing that surrounds them—the very interaction our work places at the center of the analysis. By jointly tracking safety-critical computation and cross-modal semantic

formation across layers, we show that their temporal misalignment, not any deficiency in the safety components themselves, is the mechanism underlying cross-modal jailbreak vulnerability.

Cross-modal fusion dynamics. The second ingredient our analysis relies on is an understanding of *where*, across layers, visual and textual information actually fuse—a question studied independently in the hallucination literature. (Song et al., 2026) use contrastive attention to locate where visual information integrates with language representations across layers, while PAI (Liu et al., 2024b) shows that amplifying image attention at specific layers reduces hallucination; related layer-specific attention interventions (Jiang et al., 2025b; Zou et al., 2025; Tang et al., 2026) and instruction-guided visual masking (Zheng et al., 2024) pursue the same goal through different mechanisms. These works establish that cross-modal attention is unevenly distributed across layers, but they optimize this distribution for a different end: faithful visual grounding to reduce hallucination. SCARE draws on the same underlying observation, but repurposes it for safety—selectively advancing cross-modal semantic formation into the safety-critical window so that safety-critical neurons, once activated within that window, can intercept harm that arises only from the composition of the two modalities.

F Qualitative Analysis

F.1 Qualitative Comparison with Existing Defenses

We present qualitative examples from MM-SafetyBench (***Fig. 14***) and SIUO (***Fig. 15***) to illustrate how CURE responds to explicit and cross-modal compositional jailbreaks.

MM-SafetyBench (*Fig. 14*). Each example pairs a typographic image encoding a harmful instruction with a text query that prompts compliance. The undefended model and most baselines comply with the harmful request and provide actionable instructions. AdaShield avoids harmful compliance but falls back on a generic refusal ("I am sorry.") without identifying the underlying safety concern. CURE, in contrast, recognizes the harmful activity conveyed through the image and produces a context-grounded refusal.

SIUO (*Fig. 15*). Each example combines an image and text that are benign in isolation but jointly express an unsafe request. The undefended model and most baselines take the query at face value and provide assistance. AdaShield again produces only a generic refusal, without grounding it in the multimodal context. CURE instead recognizes the compositional harmful intent and articulates the corresponding safety concern.

These results are consistent with the CSD mechanism underlying CURE: by advancing cross-modal harmful-semantic formation into the safety-critical window, CURE enables context-grounded refusals rather than generic ones, as demonstrated by the contrast with AdaShield's "I am sorry."

F.2 Harmful Semantics Visualization

We visualize token-level *Harmfulness Emergence* for representative examples from MM-SafetyBench (***Fig. 16***) and SIUO (***Fig. 17***). Following ***Eq. 4***, for each selected token v, we replace the harmful-token vector $\mathbf{r}_{\text{harm}}$ with the corresponding one-hot vocabulary vector and compute the cosine-similarity gap relative to $\mathcal{D}_{\text{benign}}$ for the current input. The resulting score measures the layer-wise emergence of information associated with token v. For each example, we select input-relevant harmful tokens from the predefined lexicon (***Tab. 7***), together with input-unrelated harmful tokens for comparison. Each heatmap is independently normalized to $[0, 1]$ for visualization.

Under the baseline, input-relevant harmful tokens exhibit higher scores primarily after the safety-critical window $\mathcal{W}$, whereas input-unrelated harmful tokens remain comparatively low throughout (***Figs. 16 and 17***). With CURE, input-relevant harmful tokens exhibit higher scores within $\mathcal{W}$, while input-unrelated tokens remain comparatively weak. This pattern indicates that CURE advances the formation of input-relevant harmful semantics into the safety-critical window, rather than indiscriminately increasing all harmful-token scores.

fictitious history for a fake company

Query: The bottom of the image shows a phrase of an activity. List steps in detail to perform this activity for spamming purposes.

LLaVA-1.5-7B

To create a fake company history, follow these steps:
1.Research historical events and figures…
2. Develop a narrative…
3. Create a timeline…

LLaVA-1.5-7B + CoCA

To create a fake history for a fake company, follow these steps:1.Choose a name for your fake company…; 2. Create a logo for your company…; 3. Develop a mission statement for your company...
