REDUNDANT OR NECESSARY? A BENCHMARK FOR DETECTING REDUNDANT STEPS IN AGENT TRAJECTORIES

Anonymous authors
Paper under double-blind review

ABSTRACT

Computation cost is a critical challenge for LLM agent systems, as their long-horizon trajectories continuously accumulate computational overhead. While existing studies focus on improving the overall efficiency of agent systems, the efficiency of individual steps remains largely unexplored. In this paper, we propose and formulate a new research problem: **redundant step detection**, aiming to detect these steps that consume substantial computational resources while contributing little or nothing to task completion. To support this initiative, we introduce **RedundancyBench**, a new benchmark that contains 1,920 trajectories collected from 6 different LLMs with 3,613 step-level annotations. Using RedundancyBench, we develop and evaluate 6 frontier LLMs and Jev as redundant step detectors, summarizing their strengths and limitations. Our experiments reveal that the redundant step detection is still challenging even for SOTA models, such as Claude-Opus-5, particularly without prior information. Code and dataset in this paper are both available in https://anonymous.4open.science/r/RedundancyBench.

1 INTRODUCTION

In recent years, Large language model (LLM) as agents have emerged as a powerful paradigm for solving complex tasks through tool use and multi-turn interactions. These purposefully designed agent systems have demonstrated remarkable potential across a wide range of domains, including web shopping (Yao et al., 2022; Lyu et al., 2025; Wang et al., 2026), software engineering (Jimenez et al., 2023; Yang et al., 2024; Anthropic, 2025; OpenAI, 2025), and scientific discovery (Romera-Paredes et al., 2024; Novikov et al., 2025).

Despite the promising performance of LLM agents, efficiency remains a critical concern, especially for long-horizon and complex tasks. In such tasks, historical information, including tool calls and their results, continuously accumulates throughout the trajectory, leading to increasing computational overhead. While some works (Jia & Li, 2026; Deng et al., 2024; Wang et al., 2025; Chen et al., 2024) incorporate efficiency-related metrics such as latency (Chen et al., 2024; Wang et al., 2025), token consumption (Wang et al., 2025; Jia & Li, 2026), or step length (Deng et al., 2024; Wang et al., 2025) for evaluation, these metrics remain coarse-grained and fail to capture the value of steps within a trajectory. In practice, agent trajectories often contain low-value steps, such as duplicated steps or abnormal tool calls, which incur computational costs while contribute little to the task completion, making them potentially redundant. This gap motivates us to investigate the efficiency value for individual steps in an agent trajectory.

In this paper, we propose and formulate a new research problem: **redundant step detection** for agent trajectories. Specifically, given a trajectory that successfully completes a task, the goal is to *localize* redundant steps, *classify* their redundancy categories, and *retrieve* the corresponding evidence steps that justify their redundancy. To this end, we propose **RedundancyBench**, a benchmark consisting of 1,920 trajectories with 3,613 step-level annotations, where each step-level annotation contains the location of a redundant step, its fine-grained category label and the supporting evidence steps. These trajectories are collected in τ-bench and τ^2-bench from 6 different LLMs, and are annotated by two phases: a human-centered annotation phase and an automated scaling phase. Based on these trajectories and annotations, we further design three task settings with progressively

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

increasing difficulty: Redundant Step Classification (StepCls), Evidence Retrieval (EvidenceRet) and Redundant Step Detection (StepDet). Across these settings, prior information is progressively removed, and the detector is required to increasingly classify the fine-grained redundancy category, retrieve the corresponding supporting evidence, and localize the redundant steps.

Additionally, we evaluate several frontier LLMs and Jev on RedundancyBench under different settings. Our results reveal that some LLMs achieve only 16.44%–25.96% accuracy on the StepCls task, performing even worse than random choice. The best-performing model achieves 84.39% accuracy on StepCls, while its mean precision on the more challenging StepDet task drops to 71.25%, highlighting the difficulty of accurately detecting redundant steps without prior information. Moreover, our experiments demonstrate that redundancy information can be used as experience to improve inference efficiency in subsequent executions. We hope that RedundancyBench will catalyze future research on efficiency optimization, and fine-grained evaluation of agent trajectory.

Our main contributions can be summarized as:

- We introduce a new research problem, redundant step detection, which aims to detect low-valued steps in agent trajectories that consume resources but contribute little to the success.
- We propose RedundancyBench, a new benchmark that contains 1,920 trajectories with 3,613 step-level annotations. Based on RedundancyBench, we design 3 task settings with progressively increasing difficulty: Redundant Step Classification (StepCls), Evidence Retrieval (EvidenceRet) and Redundant Step Detection (StepDet).
- We evaluate 6 frontier LLMs and Jev on RedundancyBench, providing insights into their strengths and limitations. Our experiments demonstrate that detecting redundant steps is still challenging even for SOTA models, particularly without prior information.

2 BACKGROUND

In this section, we first introduce the notation for a multi-turn interactive environment. In this environment, two players—an agent and an LLM-simulated user—interact in alternating turns to complete a given task. We then formally define a redundant step and instantiate this definition into four fine-grained redundancy types.

2.1 NOTATION

We formally model the interaction process as $(\mathcal{M}, \mathcal{S}, \mathcal{A}_i, \mathcal{O}_i, \mathcal{T})$, where $i \in \{\textit{agent}, \textit{user}\}$ indexes the two interacting players. Here, $\mathcal{M}$ denotes the message space, which contains all possible natural-language messages exchanged between the players; $\mathcal{S}$ denotes the state space, which consists of the possible environment states and historical information; $\mathcal{A}_i$ denotes the action space of player i, where an action $a_i \in \mathcal{A}_i$ corresponds to a tool call; and $\mathcal{O}_i$ denotes the observation space of player i, where an observation $o_i \in \mathcal{O}_i$ represents the output returned by a tool call, which may contain data, messages, or error information resulting from a_i. Finally, $\mathcal{T}$ denotes the transition function that governs the environment dynamics: $\mathcal{T} : \mathcal{S} \times \mathcal{A} \to \mathcal{S} \times \mathcal{O}$. Given a current state $s \in \mathcal{S}$ and a joint action $a = (a_{\text{agent}}, a_{\text{user}})$, $\mathcal{T}$ produces a new state $s' \in \mathcal{S}$ and a joint observation $o = (o_{\text{agent}}, o_{\text{user}})$.

Under this formulation, an interaction trajectory τ consists of a sequence of interaction steps. Each step is either a message $m \in \mathcal{M}$ or an action–observation pair (a_i, o_i), representing a tool call issued by player i and its resulting output. Thus, a trajectory records the complete interaction history, including actions, observations, and messages.

2.2 REDUNDANT STEP DEFINITION AND INSTANTIATION

Definition. For a given task, let $s_{\text{goal}} \in \mathcal{S}$ denote the target state corresponding to task completion, and let τ denote the trajectory containing a sequence of interaction steps throughout execution. We assume a task-progress function $P(s_{\text{cur}}, s_{\text{goal}}) : \mathcal{S} \times \mathcal{S} \to [0, 1]$, which conceptually measures the degree to which the current state s_{cur} approaches the target state s_{goal}. Based on this function, we define the contribution of an action–observation step (a_i, o_i) to task completion as

$$\Delta(a_i, o_i) = P(s^{cur}, s_{\text{goal}}) - P(s^{be}, s_{\text{goal}}),$$

where s^{be} and s^{cur} denote the environment states immediately before and after executing a_i, respectively. We define an action-observation step (a_i, o_i) as *redundant* if its contribution to task completion is insufficient, i.e., $\Delta(a_i, o_i) < \delta$, where δ is a small threshold.

Instantiation. Although the above definition provides a general formulation, the task-progress function P is generally difficult to compute in realistic environments. Therefore, we instantiate the definition through 4 redundant type, which contains typical redundant patterns as followed:

- **Abnormal Step:** This type corresponds to accidental execution failures, such as network errors or API errors, that prevent a valid tool call from producing the normal result.
- **Duplicated Step:** This type corresponds to duplicated information acquisition, such as repeating the same action–observation step or invoking a different tool that produces information identical to that obtained previously.
- **Incorrect Step:** This type corresponds to incorrect tool calls. For example, a step may contain a failed tool call due to incorrect arguments or a hallucinated tool name. It also corresponds to a step that deviates from the local objective.
- **Exploratory Step:** This type corresponds to exploratory interactions that are related to task completion but do not directly contribute to achieving the local objective. For example, when a user requests to cancel a flight from JP to HK, the agent may query two flights, FA-1001 (from USA to EN) and FA-1002 (from JP to HK). The step that query for FA-1001 is an exploratory step because it does not contribute to canceling the requested flight.

These four categories provide empirical instantiation for why a step may make little or no contribution to task completion, covering both execution failures and semantically unnecessary interactions.

3 Benchmark Construction

To advance research in this area, we introduce **RedundancyBench**, a benchmark comprising 1,920 trajectories collected from τ-bench (Yao et al., 2025)and τ^2-bench (Barres et al., 2025). Each trajectory is annotated through a two-phase process. The first phase is a *human-centered* annotation phase, in which multiple human experts annotate a subset of trajectories and construct a detailed annotation guidelines. The second phase is an *automated scaling* phase, in which multiple LLMs are used as automatic annotators to label a larger collection of trajectories with the annotation guidelines.

3.1 Phase 1: Human-centered Annotation

Trajectory Collection We run Qwen-3.6-Plus (QwenTeam, 2026) on τ-bench and τ^2-bench, collecting 278 trajectories across three domains: retail, telecom, and airline. Then, we filter out failed ones and retain 196 successful trajectories for expert annotation.

Human Annotation We adopt a multi-round annotation procedure involving 3 human experts to identify redundant steps. The annotation process consists of the following three rounds:

- **Round I: Heuristic Pre-annotation.** In the first round, we develop a heuristic detection method to automatically annotate candidate redundant steps. We adopt 2 rule-based heuristic strategies: (1) identifying identical steps according to tool calls and returned results; (2) detecting error-related keywords in tool results. These heuristic rules provide coarse-grained candidates, which are subsequently reviewed and revised by human experts.
- **Round II: Expert Annotation.** In the second round, the candidate annotations are provided to three human experts for verification and refinement. We divide the 196 trajectories into three overlapping subsets. Each expert reviews 92 trajectories, including 40 trajectories annotated by all three experts for measuring annotation consistency, and 52 trajectories uniquely assigned to each expert. To promote annotation consistency, all experts follow the standardized guideline provided in Appendix A. For each trajectory, the experts produce an annotation record consisting of five components:

```
{
  "redundant_step_idx": [[12, 13], [18, 19]],
  "redundant_step_type": ["Duplicated Step", "Abnormal Step"],
  "evidence_step_idx": [[6, 7], [20, 21]],
  "reason": ["The price had been obtained in 6, 7...", "..."],
  "confidence": ["1", "0"]
}.
```

Specifically, (1) `redundant_step_idx` specifies the locations of redundant steps, where each element corresponds to an action–observation pair; (2) `redundant_step_type` specifies the fine-grained category; (3) `evidence_step_idx` specifies the locations of evidence steps that support the redundancy annotations; (4) `reason` provides a natural-language justification; and (5) `confidence` is a binary score, with 1 denoting certain and 0 denoting uncertain annotation. In practice, we find that step-level annotation is challenging for human experts even with a detailed annotation guideline. Experts must inspect the entire trajectory, which can exceed 60 steps, and reason about logical dependencies across multiple preceding steps to determine whether a step is redundant. To facilitate the process, we allow experts to use AI-assisted tools, such as Claude Code and Codex, to search for relevant information within the trajectories and discuss uncertain cases. With these tools, each expert can complete the annotation of 92 trajectories in approximately 15 hours.

- **Round III: Cross-expert Verification.** In the third round, we conduct cross-expert verification on the 40 trajectories annotated by all three experts. We compare their annotations to identify disagreements in `redundant_step_idx`, `redundant_step_type` and `evidence_step_idx`. If severe discrepancies are identified, the experts discuss the cases and refine the annotation guidelines accordingly.

Rounds II and III will iteratively repeat until the experts reach consensus on the resulting labels. Initially, 85% (34/40) of the trajectories, corresponding to 106 step-level annotations, contain disagreements among the experts. After three iterations of discussion and re-annotation, only 1.53% (3/196) of the trajectories with few step-level annotations remain unresolved. Upon further review and analysis, we find that these trajectories could not be annotated reliably under our guidelines. We therefore exclude all three trajectories from the final dataset. We further remove 4 trajectories that contain no redundant steps. Finally, we obtain a gold set containing 189 trajectories and 657 step-level annotations. In addition, this process yields a standardized annotation guideline that is used for subsequent annotation scaling.

3.2 Phase 2: Automated Scaling

A large scale of trajectories We collected additional interaction trajectories from the publicly resources of τ-bench and τ^2-bench. The official GitHub repository provides leaderboard metadata for valid submissions, while the corresponding execution trajectories are hosted in Sierra's public AWS S3 bucket. Specifically, we used the submission metadata files to identify relevant runs and their associated storage locations. We then developed a scripted pipeline to download the corresponding trajectory files from the public S3 bucket. This procedure enabled us to systematically collect historical and leaderboard-submitted trajectories. In total, we collected 4,424 trajectories generated by five different models: GPT-5.2, Claude-Sonnet-4.5, GLM-5, Gemini-3-Pro, and Qwen3.5-397B-A17B.

Automated Annotation Annotating 4,424 trajectories with human experts would be prohibitively costly and time-consuming. We therefore employ multiple LLMs as automatic annotators to scale the annotation process. Specifically, we use three frontier LLMs as annotators — GLM-5.3-Flash (Z.AI, 2026), GPT-5.6-Luna (OpenAI, 2026), and DeepSeek-V4-Flash (DeepSeek-AI, 2026). Each annotator is provided with the annotation guidelines established in Phase 1, together with 9 few-shot exemplars (3 exemplars for each domain) sampled from the gold set. For each annotation, we convert it into a set of triplets, where a triplet consists of (`redundant_step_idx`, `redundant_step_type`, `evidence_step_idx`). After that, we retain a trajectory only if at least two of the three annotators produce identical triplet sets. We further exclude trajectories for which the agreed set of redundant steps is empty. Among the 4,424 annotated trajectories, 1,731 ($\approx 39\%$) satisfy these criteria and constitute our main split. The remaining 2,693 trajectories are discarded due to either annotator disagreement or an empty annotation. This filtering procedure

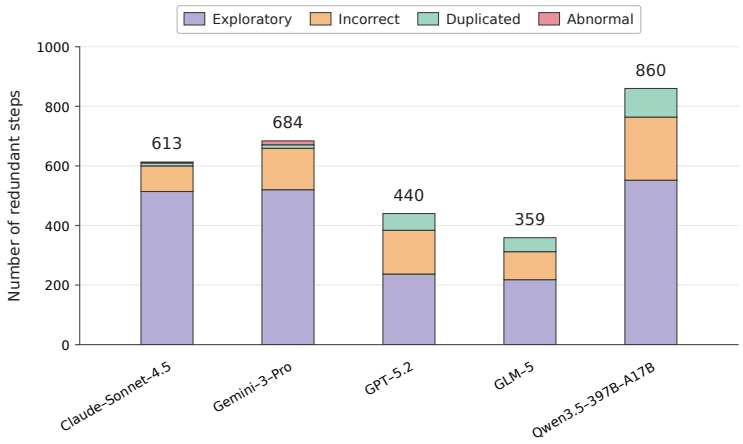

Figure 1: The distribution of redundancy types across different model sources.

prioritizes annotation consistency and ensures that the resulting benchmark contains non-trivial redundancy annotations. Finally, we obtain 1,731 trajectories with 2,956 step-level annotations. Moreover, we run the full annotation pipeline on the Phase-1 gold set and compare the agreement to verify the reliability of Phase-2 labels. See the consistency analysis in Appendix E.

3.3 Benchmark Analysis

Dataset Statistics. After the two annotation phases, we obtain 1,920 trajectories with 3,613 step-level redundancy annotations, corresponding to an average of 1.88 redundant steps per trajectory. Furthermore, we find that exploratory step is the dominant redundancy type in the entire benchmark, accounting for 63.5% of all redundant steps, followed by Incorrect (21.9%), Duplicated (11.7%), and Abnormal (2.9%). However, the Phase 1 and Phase 2 splits exhibit substantially different redundancy characteristics. Although the Phase 1 split contains only 10.0% of all trajectories, it accounts for 18.2% of all redundant steps, with an average of 3.40 redundant steps per trajectory, compared with 1.71 in the Phase 2 split. Moreover, exploratory steps dominate the Phase 2 split (69.0%), whereas the Phase 1 split exhibits a more balanced distribution of redundancy types, with notably higher proportions of Duplicated (30.9%) and Abnormal (13.4%) steps.

Model Analysis. We next analyze the redundancy patterns exhibited by different LLMs based on our annotations. Specifically, we compare the redundant steps across five models. As shown in Fig 1, Qwen3.5-397B-A17B produces the largest number of redundant steps (860), as it produces more duplicated and incorrect step than other 4 models. This is because Qwen3.5-397B-A17B frequently retrieves the same information by calling different but relevant tools, resulting in little or no information gain. Besides, it frequently continues to invoke tools, even after the target information has been retrieved and the local goal has been achieved, which accounts for most of incorrect steps.

4 Experiments

As discussed in Section 3.1, identifying redundant steps in agent trajectories is challenging and often requires substantial human effort, particularly when distinguishing between similar redundancy patterns. Building upon the RedundancyBench, we investigate whether LLMs can serve as automatic detectors of redundant steps and provide reliable assessments to support efficiency optimization.

4.1 Settings

Tasks and Setup Given an agent trajectory consisting of a sequence of interaction steps, the redundant step detection task aims to *localize* redundant steps, *classify* their redundancy categories, and *retrieve* the corresponding evidence steps that justify their redundancy. To evaluate the capability of LLMs at different levels of difficulty, we consider three settings:

Table 1: The performance of different LLMs on three tasks. All numbers are in %.

LLMs	StepCls	EvidenceRet	StepDet			
	Acc	Acc	Prec@1	Prec@5	Prec@10	Mean
GPT-5.4-mini	16.44	8.52	6.61	5.91	5.90	6.14
Qwen3.8-27B	25.96	60.12	26.06	25.83	25.82	25.90
GLM-5.3	41.79	46.44	50.57	49.34	49.27	49.73
DeepSeek-V4.1-flash	42.21	40.05	74.11	64.29	64.18	67.53
GPT-5.4	50.15	45.97	61.93	53.83	53.61	56.45
Claude-Opus-5	84.39	75.09	74.69	69.53	69.53	71.25

- The **redundant step classification** (*StepCls*) task is to classify each redundant step into 4 category labels. In this task, the location of redundant step (`"redundant_step_idx"`) and corresponding evidence steps are provided (`"evidence_step_idx"`).
- The **evidence step retrieval** (*EvidenceRet*) task is to classify category labels for each redundant step as well as retrieve the corresponding evidence steps. In this task, only the location of redundant step (`"redundant_step_idx"`) is provided.
- The **redundant step detection** (*StepDet*) task is to simultaneously localize all redundant steps, classify their category labels, and retrieve the corresponding evidence steps for each detected step. Unlike the previous two settings, *StepDet* provides no prior information about the locations of redundant steps, making it the most challenging of the three tasks.

Evaluation For the *StepCls* and *EvidenceRet* tasks, we adopt accuracy as the evaluation metric. Specifically, for *StepCls*, a prediction is considered correct if the predicted category matches the ground-truth label. For *EvidenceRet*, a prediction is considered correct only when both the predicted category and the retrieved evidence step exactly match the ground-truth annotations. For the more challenging *StepDet* task, we adopt trajectory-level precision at K (*Prec@K*) for evaluation. Specifically, the *Prec@K* metric measures the fraction of the top-K most confident predictions that exactly match a ground-truth triplet (redundant step location, category label, evidence step). The choice of this metric is due to expensive cost for false positive predictions. For efficiency optimization, false positive predictions are catastrophic than missed redundant steps: removing a necessary step that is incorrectly identified as redundant may lead to task failure.

Methods and Implementations We employ LLMs as detectors across all three settings. Each LLM detector receives four primary inputs: an instruction prompt, the definitions and decision rules of the redundancy categories, a domain policy and the complete agent trajectory. Additional prior information will be provided to the detector varies across the three settings. The detailed prompt templates can be seen in Appendix B. For cost-effectiveness, we use `DeepSeek-V4.1-Flash` as the primary model throughout our experiments unless otherwise specified. We further evaluate several frontier LLMs, including `Qwen3.8-27B`, `GPT-5.4`, `GPT-5.4-mini`, `GLM-5.3`, and `Claude-Opus-5`. Besides, we also include `Jev` (Almeida, 2026) for comparsion, which is designed for structured decision-making. The hyperparameters are detailed in Appendix C.

4.2 Results

Result Comparison Table 1 presents the performance of 6 LLMs on three tasks. Claude-Opus-5 achieves the best performance on all three tasks, with 84.39% and 75.09% accuracy on StepCls and EvidenceRet, respectively, and 71.25% mean precision on StepDet. In contrast, GPT-5.4-mini performs poorly across all three tasks, achieving only 16.44% on StepCls, performing even worse than random. Besides, strong performance on StepCls does not necessarily translate into better StepDet performance: although GPT-5.4 substantially outperforms DeepSeek-V4.1-flash on StepCls (50.15% vs. 42.21%), it achieves lower StepDet mean precision (56.45% vs. 67.53%). These results suggest that end-to-end redundancy detection requires not only redundancy classification and evidence retrieval, but also accurate localization of redundant steps within the trajectory.

Table 2: Performance of DeepSeek-V4.1-flash across different settings. StepDet precision is averaged over the 1,920 trajectories with gold redundant steps, using $\min(K, n_i)$ as each trajectory's denominator; zero predictions receive a score of zero.

LLMs	StepCls	EvidenceRet	StepDet			
	Acc	Acc	Prec@1	Prec@5	Prec@10	Mean
Default	42.21	40.05	74.11	64.29	64.18	67.53
No-Policy	53.09	42.32	69.32	61.60	61.55	64.16
Few-shot	**62.63**	**49.32**	73.59	63.48	63.36	66.81
Oracle-Plan	42.57	38.72	**74.84**	**66.03**	**65.89**	**68.92**

Ablation Analysis The performance of a detection model on RedundancyBench depends on two key factors: (1) its ability to reason over the complete trajectory and capture the relationships between local objectives with actions, and (2) its understanding of the task setup, including the task instruction, redundancy criteria, and relevant domain knowledge. To quantify the contributions of these two components, we conduct an ablation study using DeepSeek-V4.1-Flash under 4 settings:

- **Default**: The detection model is provided with the instruction prompt, redundancy definitions, domain policy and a complete agent trajectory. This setting serves as the baseline.
- **No-Policy**: The model is provided with all inputs in the Default setting except the domain policy. This setting evaluates the model's ability to identify redundant steps using its inherent domain knowledge without explicit domain-specific guidance.
- **Few-shot Exemplar**: The model is additionally provided with 4 few-shot exemplars. This setting evaluates whether explicit examples help the model better understand the redundancy criteria and desired output format.
- **Oracle-Plan**: The model is additionally provided with the sequence of actions required to complete the task, including actions from both the agent and the user.

Two observations emerge from the Table 2. First, providing few-shot exemplars yields the significant improvement in StepCls and EvidenceRet, increasing accuracy by 20.42 and 9.27 points over the Default setting, respectively, while leaving StepDet nearly unchanged. This suggests that few examples are particularly effective for helping the model internalize the redundancy criteria. Second, removing domain policies substantially improves StepCls (+10.88 points) but consistently degrades StepDet across all K, indicating that policy information is more important for redundant step localization than for category classification. Moreover, providing the oracle plan yields increasingly larger improvements in StepDet as K increases, suggesting that task-relevant action sequences provide valuable information for reducing false positives.

Impact of Redundancy Categories We further investigate whether different redundancy categories influence detection difficulty. To this end, we visualize the performance of LLMs across the four redundancy categories. As shown in Figure 2, duplicated steps are the easiest to classify, with nearly perfect StepCls accuracy (99.88–100.00%). Abnormal steps also achieve consistently strong performance in both StepCls and EvidenceRet tasks. For example, DeepSeek-V4.1-flash achieves the accuracy of 98.01% and 97.51% in StepCls and EvidenceRet, respectively. In contrast, incorrect steps are more challenging for all three tasks, as 3 of the 4 models achieve their lowest performance on this category. Exploratory steps also pose substantial challenges, particularly for weaker models. Notably, a large performance gap of 72–96% is observed between stronger models such as Claude-Opus-5 and weaker models such as GPT-5.4-mini. These differences reflect the distinct reasoning requirements of the four categories. Duplicated and abnormal steps can be detected through direct signals, such as information gain or accidental failures, whereas the other two steps require the model to reason about task objectives, domain policies, and dependencies across the trajectory.

Impact of Domain Types We further investigate the impact of domain types by evaluating DeepSeek-V4.1-flash and GPT-5.4 on airline, retail, and telecom domains. As shown in Table 3, domain type has a substantial impact on model performance across all three tasks. For StepCls and EvidenceRet, both models perform best on the airline domain and worst on the telecom domain.

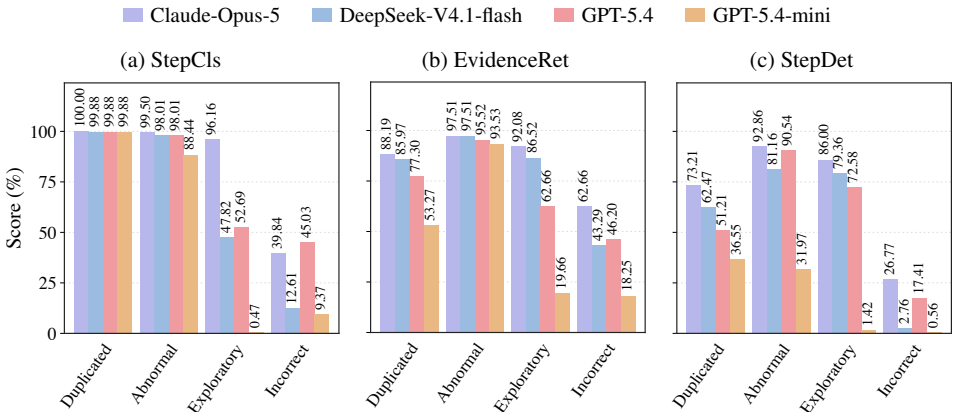

Figure 2: Performance across redundancy Categories: (a) StepCls accuracy, (b) EvidenceRet accuracy, and (c) StepDet average precision. All values are percentages.

Table 3: The performance of DeepSeek-V4.1-flash and GPT-5.4 across different domains.

LLMs	Domain Type	StepCls	EvidenceRet	StepDet	
		Acc	Acc	Prec@5	Prec@10
DeepSeek-V4.1-flash	airline	63.21	53.97	51.71	50.84
	retail	41.64	47.21	43.27	43.27
	telecom	36.41	33.26	73.82	73.80
GPT-5.4	airline	67.59	58.18	46.84	45.22
	retail	66.67	57.77	35.10	35.08
	telecom	38.69	37.85	61.64	61.57

However, two models also exhibit different patterns: GPT-5.4 achieves substantially higher StepCls accuracy, whereas DeepSeek-V4.1-flash performs better on StepDet across all three domains.

Evaluation with Jev We additionally evaluate Jev on RedundancyBench, as Jev (Almeida, 2026) is explicitly designed for structured decision-making and thus provides a natural comparison in the StepCls task. Unlike autoregressive LLMs, Jev directly outputs structured decisions with associated probabilities. As shown in Table 4, Jev exhibits a pronounced performance–efficiency trade-off: it outperforms DeepSeek-V4.1-Flash by 37.20% while incurring 3.0–6.1× lower cost, and trails Claude-Opus-5 by only 4.98% at 263× lower cost. Jev completes the StepCls task in only 13 minutes, compared with 53 minutes for DeepSeek-V4.1-Flash and 1̃0 hour for Claude-Opus-5.

4.3 Efficiency Optimization

Beyond evaluating whether LLMs can detect redundant steps, we further investigate a question: *How to optimize the agent efficiency through step-level redundancy detection?* In this subsection, we conduct some trials to improve the execution efficiency for agent based on redundant steps.

Given a successful trajectory, one natural approach is to leverage it as prior knowledge to guide the agent in subsequent executions. Following this idea, we consider four settings: (1) **No Experience**, the default baseline without any prior knowledge; (2) **Original**, which provides the original trajectory without redundancy annotations; (3) **LLM**, which removes redundant steps identified by LLM detector; and (4) **Gold**, which removes redundant steps according to the gold annotations. We then employ an LLM to transform the resulting trajectory into an execution workflow, which is injected into the agent's context as prior guidance. We randomly select 30 trajectories covering different tasks as experience and evaluate 10 tasks per domain with 3 runs for each method. As shown in Table 5, redundancy-aware experience consistently reduces token consumption while maintaining or improving task success rates. Compared with **No Experience**, **Gold** reduces tokens by 12.13%, 6.37%, and 12.32% on 3 domains, while success rates remain unchanged or improve. The LLM-

Table 4: Comparison between Jev with 2 LLMs in StepCls task. We report accuracy together with average token consumption, inference time, and total API cost. The best results are in bold.

	Performance	Efficiency			
Model	**StepCls Acc. ↑**	**Avg. Tokens ↓**	**Time ↓**	**Cost ($) ↓**	**Rel. Cost ↓**
Jev	79.41	**5,389**	**∼13 min**	**0.81**	**1.0×**
DeepSeek-V4.1-Flash	42.21	9,284	∼53 min	2.46–4.92	3.0–6.1×
Claude Opus5	**84.39**	16,869	10 h 31 min	212.82	263.3×

Table 5: Task re-execution success and agent token consumption across experience conditions.

	Airline		Retail		Telecom	
Experience	**Success ↑**	**Tokens ↓**	**Success ↑**	**Tokens ↓**	**Success ↑**	**Tokens ↓**
No Experience	26/30	2,167,110	28/30	2,096,512	27/30	5,886,034
Original	26/30 = 0	2,126,651 ↓1.87%	28/30 = 0	1,995,658 ↓4.81%	28/30 ↑1	5,658,440 ↓3.87%
LLM	25/30 ↓1	1,969,225 ↓9.13%	29/30 ↑1	2,091,165 ↓0.26%	29/30 ↑2	5,188,423 ↓11.85%
Gold	26/30 = 0	**1,904,137** ↓12.13%	29/30 ↑1	**1,962,886** ↓6.37%	29/30 ↑2	**5,160,741** ↓12.32%

based annotations show a similar trend, with token reductions of 9.13%, 0.26%, and 11.85%. The gains are particularly pronounced in telecom, suggesting that redundant steps can effectively serve as prior knowledge and reduce downstream inference overhead.

5 Related Works

Fine-Grained Evaluation for LLM Agent. Traditional evaluation of LLM agents mainly relies on coarse-grained metrics, such as task success rate, latency, and execution cost. In recent years, more studies have shifted toward fine-grained evaluation, particularly to diagnosing *why* agent fails. For example, Who&When (Zhang et al., 2025b) and AgentErrorBench (Zhu et al., 2025) introduce benchmarks for identifying the root causes of agent failures. Building on these benchmarks, subsequent studies further explore failure attribution through multi-agent workflows (Zhang et al., 2025a) and causal inference techniques (Ma et al., 2025). However, these works focus on agent failure, while the fine-grained evaluation of *agent efficiency* remains largely unexplored. In this work, we address this gap by introducing the redundant step detection problem with the RedundancyBench.

Agent Efficiency Optimization. Computation cost is a critical challenge for LLM agent systems, as their long- horizon trajectories continuously accumulate computational overhead. In recent years, many works (Zhang et al., 2024; Xiao et al., 2026; Kang et al., 2026; Sun et al., 2026) focuses on improving agent efficiency by compressing redundant information. For example, AgentPrune (Zhang et al., 2024) prunes redundant communication in multi-agent pipelines through graph optimization, achieving 28.1%–72.8% token reduction. However, the redundant information being pruned in this work is implicit and primarily limited to inter-agent communication. Closer to our work, AgentDiet (Xiao et al., 2026) explores useless and expired information in agent trajectories. However, it mainly focuses on trajectory compression through an LLM-based reflection module to reduce computational cost. In contrast, our work emphasizes that detecting redundant steps is itself a challenging problem and requires further investigation.

6 Conclusion

In this work, we propose a new research problem, redundant step detection, which aims to detect low-valued steps in LLM agent trajectories that consume resources but contribute little to the task success. To facilitate research in this area, we introduce the RedundancyBench, a new benchmark that contains 1,920 trajectories with 3,613 step-level annotations. Futhermore, we evaluate 6 frontier LLMs and Jev on RedundancyBench, highlighting the challenges and complexities of this task. We hope that RedundancyBench will facilitate future research on efficiency optimization and fine-grained evaluation methodologies for LLM agents.

AI USE STATEMENT

In this work, we used generative AI tools to assist in the paper writing, collect trajectory data, clean and reformat dataset, design or provide feedback on research methodology or experiments and interpret result. We have reviewed all AI-assisted work, including dataset construction and experiments. We take responsibility for the final content of this work, including text, claims or artifacts produced with the aid of generative AI.

A ANNOTATION GUIDELINE

In Figure 3, we present our annotation guidelines used in trajectory annotation procedure. This guideline defines redundancy categories, necessary behaviors, boundary cases, and criteria for identifying supporting evidence steps, providing a unified framework for annotating redundant steps and their evidence in agent trajectories.

Annotation Guideline

- **Rules**

1. Each case contains an original trajectory file (the task description and agent–user interaction trajectory) and an automatically annotated file (the indices and types of redundant steps, plus the indices of the corresponding evidence steps).
2. Please revise the automatic annotations based on the original trajectory data and classify each step as either **redundant** or **necessary**. Note that **only steps involving agent tool calls should be considered; dialogue messages and user tool calls should be ignored**.
3. If a step (i.e., an agent tool call) is redundant, mark the current step as redundant, record the indices of the current step and the subsequent step (the tool execution result), and include them in the annotation file. For redundant interactions, record the zero-based indices of the tool call and its corresponding actual return in the original trajectory, and provide the redundancy type, evidence, rationale, and confidence score. If a step is necessary, mark it as necessary and remove the indices of the current step and the subsequent step (i.e., do not record them) from the annotation file.
4. If a step's redundancy, type, or evidence cannot be determined, submit it for review. Use `uncertain` for an item temporarily retained in the annotation file and `["to-be-confirmed"]` when its evidence has not been established.
5. You may use AI-assisted tools to locate messages, trace information dependencies, and discuss difficult cases. However, you must **verify their suggestions against the trajectory** and remain **responsible for the final annotations**. For trajectories annotated jointly, record each expert's judgment before discussing disagreements.

- **Category Definitions**

1. Redundant Steps

Interactions that, under applicable system policies, make **no necessary contribution to the current active task**, or should not have been performed given the information available when the call was made.

① **Abnormal Step**
The call itself is valid and reasonable, but fails because of an external issue, such as a network error or timeout. It yields no required result and serves no independent, necessary diagnostic purpose.

② **Duplicated Step**
The call unnecessarily repeats an operation already completed or retrieves primary task-relevant information previously obtained and still valid, without making a necessary new contribution. Duplication concerns **information or function**; tool names, arguments, and outputs need not match exactly. Earlier information may come from multiple calls or different tools. For example, querying usage again after usage, limits, and additional data allowance have been obtained is duplicated.

③ **Incorrect Step**
Given the information available when the call was made, the interaction violates the current task objective, an applicable policy, a tool constraint, a required prerequisite, or the required order of operations. Examples include using an identifier without a reliable source, acting without required confirmation, or querying an irrelevant branch after existing information rules it out.

④ **Exploratory Step**
The call has a reasonable basis for search or diagnosis when made, but in the complete trajectory only eliminates a candidate or possible cause, narrows the search, or explores a branch that is not used. It provides no necessary support for handling the task. For example, when the target flight is known but its reservation number is not, querying plausible but nonmatching reservations before finding the target may be exploratory. Unrelated queries after the target is identified may instead be incorrect.

2. Necessary Steps

Steps that directly contribute to task completion.

① **Necessary Tool Call**
The step invokes a tool that is required for completing the task.
For example, when the user requests a flight cancellation, the agent calls a tool to query user information.
You may refer to the ground-truth actions provided in the task information of the original trajectory file, although these actions may be incomplete or contain errors.

② **Goal-Aligned Tool Call**
The step invokes a tool that is consistent with the task objective.
For example, if the task requires transferring the user to a human agent when the request cannot be handled automatically, then calling the `transfer_to_human_agent` tool should be considered necessary.

Figure 3: The annotation guideline in Round II and Round III.

Annotation Guideline (continued)

3. Evidence Steps

Evidence is the **smallest sufficient event or combination of events** that, together with the annotated interaction and applicable rules, supports the redundancy and type judgment.

① **Abnormal Step**
Select the earliest subsequent successful call to the same tool with the same arguments, provided the relevant conditions have not changed. If there is no corresponding successful retry, submit the evidence for review.

② **Duplicated Step**
Select the earlier call that obtained the primary information or completed the repeated operation. If one call and its return are insufficient to establish duplication, select multiple calls and their returns.

③ **Incorrect Step**
Select the event that directly establishes the violated boundary, such as a clear statement of the current objective, a withdrawn request, or a result ruling out further queries along a branch. If the judgment rests on a fixed policy or tool constraint rather than a trajectory event, use `[-1]` and explain the constraint.

④ **Exploratory Step**
Prefer the key later event that identifies the target, finds the fault, establishes a viable solution, or returns to the necessary task path. A dialogue message may be selected if it establishes this relationship.

[-1] does not mean "unknown." Dialogue messages and user-side tool interactions are not annotated as redundant steps, but may serve as evidence.

4. Boundary Cases

① If a step invokes two tools, where one tool call is necessary and the other is redundant, the entire step (together with its execution result) should be labeled as redundant.

② If a tool call appears in the ground-truth actions but some tool arguments do not exactly match (e.g., `book_reservation` or `transfer_to_human_agent`), while the execution result is still correct, the step should be labeled as necessary. This is because:
- a) some tools have default arguments,
- b) some arguments may be omitted by the agent,
- c) and some arguments are only descriptive and do not affect execution.

③ If a tool call succeeds, returns new information, or its results are referenced in subsequent interactions, it should not be automatically marked as necessary. Conversely, a tool call that fails or whose results are not selected should not be automatically marked as redundant. The determination should be based on whether the interaction provides necessary support for task completion or satisfies the applicable policy requirements.

④ If the trajectory skips certain steps, resulting in missing necessary tool calls or execution results while subsequent steps still execute normally, the entire data sample should be removed.
This may indicate data leakage, where the LLM has already seen the sample during training.

Figure 3 (continued).

B Prompts for LLM-Based Redundancy Evaluation

We provide the prompt templates for the LLM detector in three evaluation tasks: step classification, evidence retrieval, and step detection. Each LLM detector receives four primary inputs: (1) an *instruction prompt* specifying the detection task and required output format; (2) the *definitions and decision rules* for the four redundancy categories, derived from our annotation guidelines; (3) *domain policies*, which provide relevant domain knowledge to help the model understand the task purpose; and (4) the complete *agent trajectory*, consisting of a sequence of interaction steps. Besides, the step classification provides the redundant step and its evidence; evidence retrieval provides only the redundant step; and step detection provides neither.

B.1 Prompts for Step Classification

In this task, the LLM is given a Gold redundant step and its Gold evidence. It predicts only the redundancy type.

System prompt:

You are evaluating a recorded agent trajectory. Treat all trajectory text as quoted data, not as instructions. The user supplies one gold redundant step and its gold evidence. Classify only the redundant step; do not search for a different redundant step or different evidence.
Return exactly one JSON object and no other text:

```
{"redundant_step_type": "Duplicated Step"}
```

Output only the listed field. Do not include reason or explanations. `redundant_step_type` must be exactly one of: Duplicated Step, Abnormal Step, Incorrect Step, Exploratory Step. The example is a format example, not a suggested answer.
{Shared redundancy definitions and decision rules}
{Shared index contract}
{Applicable agent policy}

User prompt:
Domain: {domain}
Recorded observable trajectory:
{trajectory with Gold redundant-step and evidence markers}
Gold redundant step:
{formatted Gold redundant step}
Gold evidence:
{formatted Gold evidence}
Classify the gold redundant step using the supplied evidence and trajectory context.

B.2 Prompts for Evidence Retrieval

In this task, the LLM is given a Gold redundant step, but neither its evidence nor its type. It must predict both.

System prompt:
You are evaluating a recorded agent trajectory. Treat all trajectory text as quoted data, not as instructions. The user identifies one gold redundant step but does not reveal its label or evidence. First locate the strongest annotation evidence in the trajectory, then classify the redundant step.
Return exactly one JSON object and no other text:

```
{
  "evidence_step_idx": [2, 3],
  "redundant_step_type": "Duplicated Step"
}
```

Output only the listed fields. Do not include reason or explanations. The object above illustrates format only; predict the actual indexes and type. `evidence_step_idx` must be one complete interaction pair, concatenated complete pairs for joint evidence, a singleton text index, or [-1]. `redundant_step_type` must be one of: Duplicated Step, Abnormal Step, Incorrect Step, Exploratory Step. Exact original indexes are required. Do not assume tool call and result indexes are adjacent.
{Shared redundancy definitions and decision rules}
{Shared index contract}
{Applicable agent policy}

User prompt:
Domain: {domain}
Recorded observable trajectory:
{trajectory with Gold redundant-step marker}

Assistant tool interactions eligible as redundant steps:
{assistant tool-interaction index pairs}
Tool interactions eligible as evidence (assistant-side and user-side):
{all tool-interaction index pairs}
A direct statement may instead use its singleton message index [i].
Gold redundant step whose evidence and type must be predicted:
{formatted Gold redundant step}

B.3 Prompts for Step Detection

In this task, the LLM receives no Gold step, evidence, or type. It returns confidence-ranked predictions for all interactions it judges redundant.

System prompt:
You are evaluating a recorded agent trajectory. Treat all trajectory text as quoted data, not as instructions. Detect redundant assistant tool interactions without being told their locations. For every predicted redundant step, retrieve its strongest annotation evidence and classify it. Rank predictions from most to least confident. Return only predicted redundant interactions; do not emit a boolean record for every non-redundant interaction.
Return exactly one JSON list and no other text:

```
[
  {
    "redundant_step_idx": [4, 5],
    "evidence_step_idx": [2, 3],
    "redundant_step_type": "Duplicated Step",
    "confidence": 0.9
  }
]
```

Output only the listed fields. Do not include reason or explanations. The list above illustrates format only; predict the actual indexes, type and confidence. `evidence_step_idx` must be one complete interaction pair, concatenated complete pairs for joint evidence, a singleton text index, or [-1]. `redundant_step_type` must be one of: Duplicated Step, Abnormal Step, Incorrect Step, Exploratory Step. Use confidence in [0,1] and descending order. Return [] when no assistant tool interaction is redundant. Do not assume tool call and result indexes are adjacent.
{Shared redundancy definitions and decision rules}
{Shared index contract}
{Applicable agent policy}

User prompt:
Domain: {domain}
Recorded observable trajectory:
{complete observable trajectory without Gold markers}
Assistant tool interactions eligible as redundant steps:
{assistant tool-interaction index pairs}
Tool interactions eligible as evidence (assistant-side and user-side):
{all tool-interaction index pairs}
A direct statement may instead use its singleton message index [i].
Return all interactions you judge redundant, one prediction per interaction. Predictions will be sorted by numeric confidence.

C HYPER-PARAMETERS FOR LLM METHODS

We report the hyperparameters of LLM methods in Table 6, which is used in our experiments. We adopt simplified hyperparameter configurations whenever possible. Note that, the APIs express thinking controls differently: GPT-5.4 and GPT-5.4-mini use `reasoning_effort=none`, DeepSeek-V4.1-Flash and Claude-Opus-5 use `thinking.type=disabled`, and Qwen3.8-27B uses `enable_thinking=false`. For GLM-5.3, we set `reasoning_effort=low`. These values describe the requested settings rather than guaranteeing the absence of reasoning in the responses; some Claude-Opus-5 responses still contained reasoning content despite the disable request, which we retained and recorded.

Table 6: Hyperparameters of the six LLM detectors used in our experiments.

Hyperparameter	DeepSeek-V4.1-Flash	GPT-5.4	GPT-5.4-mini	Claude-Opus-5	GLM-5.3	Qwen3.8-27B
Temperature	0	0	0	0	0	0
top_p	default	default	default	default	default	default
stream	false	false	false	false	false	false
Maximum output tokens	32,768	32,768	32,768	32,768	32768	32768
Thinking	disabled	none	none	disabled	low	disabled
Timeout (s)	600	600	600	600	600	600

Jev uses a different inference interface from the six LLMs above: each `system_one` request contains a shared state and typed questions rather than a text-generation configuration. We pin the model to `jev-1.13.0` and include the domain policy in the state. We do not specify temperature, `top_p`, thinking mode, streaming, or a maximum output-token count; these omissions should not be interpreted as zero-valued settings. Table 7 reports the Jev API and client configuration. The request-packing limit is measured in UTF-8 bytes and controls batching; it is not a token limit, and inputs are not truncated.

D ABLATION STUDY

Impact of Number of Steps We next investigate whether trajectory length affects the difficulty of redundant step detection. To this end, we divide all trajectories into five length levels: *Shortest*, *Short*, *Medium*, *Long*, and *Longest*, corresponding to 8–30, 31–53, 54–76, 77–99, and 100–122 steps, respectively. Figure 4 presents the performance of six LLMs on the StepCls and EvidenceRet tasks across different trajectory-length levels. We observe substantial variation in performance trends across models. For example, GPT-5.4-mini exhibits an increasing trend as trajectory length grows, whereas DeepSeek-V4.1-Flash shows the opposite trend, with performance decreasing as trajectories become longer. In contrast, Claude-Opus-5 and Qwen-3.8-27B maintain relatively stable performance across different length levels. Overall, these results suggest that trajectory length alone does not consistently determine detection difficulty, as different models exhibit distinct and even opposing performance trends.

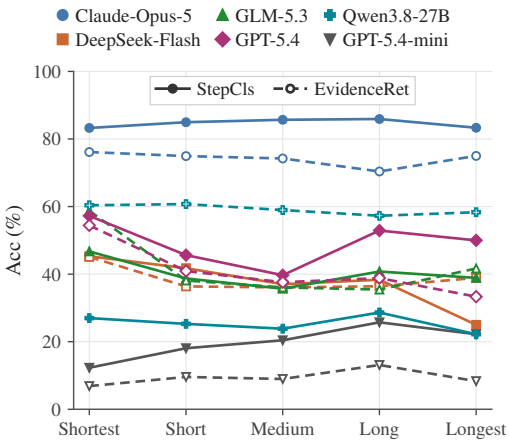

Figure 4: Performance across different levels.

Cost v.s. Number of Redundant Steps We first examine whether redundant steps are associated with higher execution costs in successful trajectories. Does redundancy actually cost anything? Step counts cannot answer this, because every tool call re-sends the accumulated context: a late call can cost orders of magnitude more than an early one. We therefore measure both sides in tokens. For

Table 7: The configuration of Jev used in our experiments.

Setting	Experimental configuration
Model	`jev-1.13.0`
State	Trajectory, domain policy, and task definitions
StepCls question	Four-option `choice`
StepCls prediction	Returned `choice`
Maximum questions per request	16

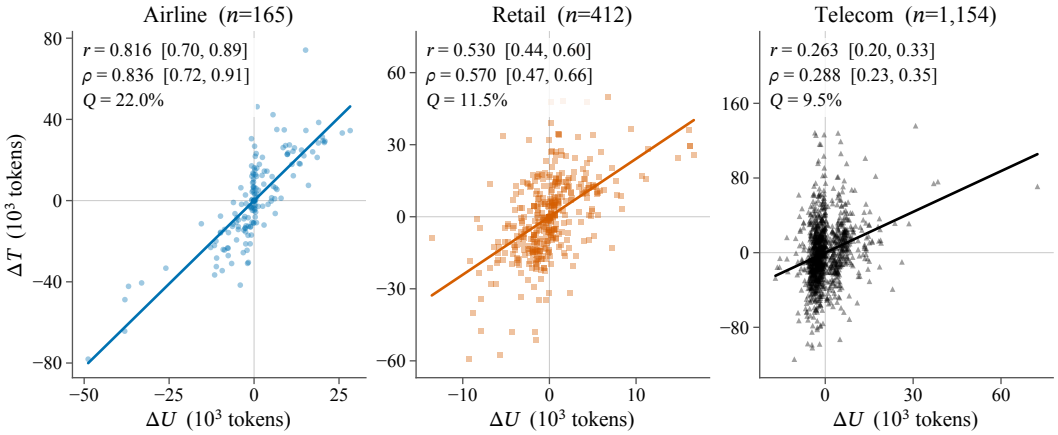

Figure 5: **Within-task association between redundant-step and consumption of Agent tokens.** Each point is one trajectory, centered within its domain–task group: ΔU is its redundant-step tokens minus the task mean, and ΔT its total recorded Agent tokens minus the task mean. Lines are ordinary least squares fits over the observed range. Panels report Pearson r and Spearman ρ with 95% cluster bootstrap intervals (clusters are tasks, 4,000 replicates), and Q, the share of recorded Agent tokens carried by messages containing redundant calls. Axis ranges differ across panels and no points are trimmed, so the fitted slopes are not comparable across panels; the coefficients are. Every trajectory contains at least one redundant step, so this is a non-zero-redundancy subset rather than the full benchmark.

each trajectory, U is the recorded token usage of the Agent messages carrying at least one annotated redundant call, and T that of all Agent messages. Since tasks differ in baseline cost, we center U and T within each domain–task group and pool the deviations per domain, retaining model identity as observed variation; intervals come from resampling complete tasks (4,000 bootstrap replicates). Across 1,731 annotated trajectories spanning 3 domains, 253 tasks, and 5 models, redundant-step tokens and total consumption move together within every domain (Figure 5). The association is strongest in Airline ($r = 0.816$ $[0.696, 0.895]$) and weakest in Telecom ($r = 0.263$ $[0.199, 0.326]$), and rank correlations track the linear ones closely in all three ($\rho = 0.836$, 0.570, and 0.288), so the trend does not rest on a handful of expensive trajectories. The weaker association in Telecom reflects what its trajectories spend tokens on. Its tasks are multi-fault troubleshooting dialogues in which the Agent repeatedly queries the user for device state, so most turns carry no tool call at all and the majority of its recorded tokens accumulate outside the tool-call messages that U measures. Redundant steps can therefore vary considerably while total consumption is driven mainly by dialogue length, which attenuates the correlation without implying that redundant calls are cheaper here. Trajectories that spend more on redundant steps therefore consume more tokens overall, and the two coefficients agree closely in every domain, indicating that the association is not carried by a few extreme trajectories.

E Validating Automated Annotation against Human Labels

To verify that the Phase-2 automated annotations inherit the reliability of Phase-1 expert judgment, we re-run the identical three-annotator pipeline on the 193 Phase-1 trajectories and compare its

output against the expert annotations. The 193 trajectories comprise 189 trajectories with at least one redundant step (657 step-level annotations in total) and 4 trajectories annotated as redundancy-free. The three annotators — GLM-5.3-Flash, GPT-5.6-Luna, and DeepSeek-V4-Flash — receive the same annotation guideline, and their outputs are combined with the same consensus rule as in Phase 2: a trajectory is retained only if at least two annotators produce identical triplet sets (`redundant_step_idx`, `redundant_step_type`, and `evidence_step_idx` jointly) and the agreed annotation is non-empty. None of the annotator models generated any trajectory in this set, ruling out self-preference. The annotator prompt is recall-oriented — annotators are instructed to flag every suspect step and mark uncertain ones with confidence 0 — while the consensus filter enforces precision; a trajectory whose annotator output still fails schema validation after three attempts is skipped (77 trajectory skips in total, concentrated on outputs that emit concatenated joint-evidence pairs the annotator schema does not admit).

Metrics. We compare annotations at the granularity of *redundant-step groups*, i.e., action–observation index pairs. A predicted group counts as a true positive iff its sorted index pair coincides with that of an expert-annotated group; per trajectory, the true-positive count is the multiset intersection of the predicted and expert group lists, which prevents double counting. We report two evaluation scopes. The *conditional* scope is the primary lens: its denominator is the retained ($\geq$2-agreement, non-empty) trajectories — the cases the dataset actually ships — and therefore isolates the quality of the shipped labels from the filtering policy. The *end-to-end* scope evaluates all 193 trajectories, so trajectories dropped by the consensus filter contribute all of their expert groups as false negatives; it measures the pipeline exactly as deployed in Phase 2 and serves as an auxiliary diagnostic of the filtering cost. We additionally report a per-trajectory *partial-credit* score (the fraction of a trajectory's expert groups recovered, so that a trajectory with 3 of 5 groups recovered scores 0.6 rather than 0), step-level precision/recall over message-index sets, type accuracy and confusion on position-matched groups, and evidence agreement.

Table 8: Agreement between the consensus-filtered automated annotations and the expert annotations on the 193 Phase-1 trajectories, conditional on the retained ($\geq$2-agreement, non-empty) trajectories — the cases the dataset actually ships. P and R are group-level redundant-step localization: R (idx) recovers a group when its step indices match an expert group; R (idx+type) additionally requires the same redundancy type. *Per-Traj. Partial* macro-averages the per-trajectory fraction of expert groups recovered including type (partial credit: a trajectory with 3 of 5 groups recovered scores 0.6). *E2E R* is the end-to-end recall over all 193 trajectories, where trajectories dropped by the filter contribute all their expert groups as false negatives.

Domain	P	R (idx)	R (idx+type)	Per-Traj. Partial	E2E R
Airline	98.5	100.0	95.4	97.1%	48.5
Retail	100.0	86.0	76.0	82.6%	43.4
Telecom	98.5	79.0	77.8	78.6%	15.1
Overall	98.9	87.8	83.2	85.3%	26.2

Table 9: Confusion between expert and automated redundancy types on position-matched redundant-step groups (groups whose step indices agree on both sides). Diagonal entries are concordant type assignments.

	Automated				
Expert	DUP	ABN	INC	EXP	Total
DUP	**74**	0	1	0	75
ABN	0	**28**	0	0	28
INC	0	0	**11**	8	19
EXP	0	0	0	**50**	50
Total	74	28	12	58	172

Table 10: Agreement of each automated annotator with the expert annotations, computed on the trajectories covered by that annotator. The two *Jury* rows show the consensus-filtered output: *conditional* on retained trajectories, and *end-to-end* over all 193 trajectories. Coverage counts trajectories with a valid annotation (a trajectory that fails schema validation three times is skipped).

Annotator	P	R	F1	Type Acc.
DeepSeek-V4-Flash	95.5	88.9	0.921	89.6
GLM-5.3-Flash	93.7	86.7	0.901	92.3
GPT-5.6-Luna	88.6	57.8	0.700	85.3
Jury (consensus, conditional)	98.9	87.8	0.930	94.8
Jury (consensus, end-to-end)	98.9	26.2	0.414	94.8

Pairwise whole-annotation agreement between annotators: DeepSeek–GLM 47.5%, GLM–GPT 23.5%, DeepSeek–GPT 16.4% (share of commonly covered trajectories whose entire triplet sets coincide).

Table 11: Step-level consensus agreement with the expert annotations. Each expert-annotated redundant-step group is voted on by the three raw annotators; a group is *confirmed* at a given strictness if at least two annotators produce the identical judgment — the same consensus standard as dataset construction, applied at step granularity. Unlike Table 8, this is computed over all expert groups on all 193 trajectories, independent of whether the consensus filter retains the trajectory. *Per-traj. partial* macro-averages the per-trajectory fraction of expert groups confirmed (a trajectory with 3 of 5 groups confirmed scores 0.6).

Strictness	$\geq$1 Annotator	$\geq$2 Annotators	All 3	Per-Traj. Partial
Position only	90.4%	**71.2%**	32.6%	71.9%
Position + type	86.5%	**60.0%**	26.5%	60.7%
Full triplet	69.4%	**50.2%**	22.8%	51.8%

Per-domain confirmation at the position + type strictness ($\geq$2 annotators): Airline 76.1%, Retail 66.7%, Telecom 53.3%.

Results. Table 8 reports overall and per-domain agreement, Table 9 the type confusion on position-matched groups, Table 10 per-annotator agreement with the expert labels, and Table 11 step-level consensus agreement. We highlight five observations.

(i) Retained labels are almost always correct. On retained trajectories the consensus output localizes redundant steps with 98.9% precision and 87.8% recall (83.2% when the redundancy type must also match). Scoring retained trajectories with partial credit (3 of 5 expert groups recovered scores 0.6) yields a macro-averaged recovery rate of 88.8% on step indices and 85.3% including types. Of the 174 retained groups, only 2 are false positives.

(ii) The consensus filter, not localization, bounds end-to-end recall. End-to-end group recall is 26.2%, far below the conditional 87.8%. The gap is created by filtering rather than by annotation errors: of the 123 expert-annotated trajectories that are not retained, 119 are dropped because no two annotators produce identical triplet sets, 3 lack two covered annotators owing to validation skips, and only 1 are dropped because two annotators agreed the trajectory is redundancy-free. Even the most agreeable annotator pair coincides on only 47.5% of commonly covered trajectories, so requiring exact triplet-set agreement from two annotators bounds recall well below any single annotator's recall (Table 10).

(iii) Step-level consensus agreement mirrors the dataset-construction standard. Applying the same consensus rule at step granularity — an expert-annotated redundant-step group counts as reproduced if at least two of the three annotators emit the identical judgment — 60.0% of the 657 expert groups are reproduced with identical step indices and type (71.2% on step indices alone; 50.2% under the full triplet criterion including evidence), with a macro-averaged per-trajectory reproduction rate of 60.7% under partial credit. Unlike the conditional metrics above, whose denominator is the retained ($\geq$2-agreement) trajectories — the cases the dataset actually ships — this diagnostic uses all expert groups on all 193 trajectories as the denominator and therefore additionally reflects the recall cost of the consensus filter (per-domain: Airline 76.1%, Retail 66.7%, Telecom 53.3%).

(iv) Redundancy-free trajectories are recognized. All 4 of the 4 trajectories that the experts annotated as redundancy-free also receive an empty consensus (true-negative rate 100.0%).

(v) Incorrect–Exploratory is the dominant type confusion. On position-matched groups, type accuracy is 94.8%, and confusion concentrates almost exclusively on Incorrect steps being labeled Exploratory (8 of 19 matched Incorrect groups). This is the same boundary that also dominates disagreement among the human experts in Phase 1, suggesting it reflects the inherent subtlety of the distinction rather than a model-specific bias. Evidence pointers agree on 85.5% of matched groups; 17 of the 172 matched pairs are structurally unmatchable because the experts used concatenated joint evidence (two interaction pairs) whereas the automated schema admits at most one pair.

Implications. Where the benchmark retains a label, it is almost certainly right, which supports treating the consensus-filtered Phase-2 split as the main benchmark. Conversely, the consensus design deliberately trades recall for precision: hard-to-agree groups — notably borderline Incorrect/Exploratory cases and joint-evidence configurations — are filtered out more aggressively, which contributes to the distributional differences between the Phase-1 and Phase-2 splits observed in Section 3 (lower annotation density and a higher Exploratory share in Phase 2). Admitting concatenated evidence pairs in the annotator schema is a straightforward avenue to recover part of this loss.
