AUTHDIFF: MEASURING AND CONSTRAINING AUTHORIZATION DRIFT IN LLM AGENTS

Anonymous authors
Paper under double-blind review

ABSTRACT

LLM agents update their authorization policies during execution to accommodate task requirements revealed by tool results. Existing agent-security evaluations focus on attack success rate and task completion, leaving changes to the policies themselves unmeasured. We identify and define **authorization drift**: successive policy updates permit requests that were initially denied, without a supporting trusted grant. Drift can make the monitor permit later messages, file changes or transfers beyond the initial authorization boundary, even when tasks succeed and injections fail. We introduce **AuthDiff** to measure and constrain drift. AuthDiff compares decisions on the same requests before and after each update, checks expansions against the initial policy and trusted grants, and uses an online guard to reject flagged updates. We observe drift in two dynamic authorization systems, Progent and DRIFT. All eleven evaluated agent models exhibit drift under Progent. On GPT-5.6-Luna, the guard reduces drift events per update by 86.9% while recording the same number of successful tasks. Our findings show that constraining authorization drift is essential to securing LLM agents throughout task execution.

1 INTRODUCTION

With ReAct-style tool calling (Yao et al., 2023; Schick et al., 2023; Qin et al., 2024), LLM agents read and write mail and files, call APIs, and initiate transfers and bookings. The required permissions often become clear only during execution: an agent learns who to reply to after opening an email, or which flight to book after querying availability. A static policy may pre-allow too much or block a legitimate task during execution. Systems use *dynamic authorization*: adjusting the permitted action set during execution by rewriting the runtime policy, as in Progent (Shi et al., 2025), or re-selecting a subplan within a predeclared authorization boundary (Wang et al., 2026b).

Existing agent-security evaluations focus on attack success rate (ASR) and task utility: whether an injection achieves the attacker's goal and whether the agent completes the user's task (Debenedetti et al., 2024; Zhan et al., 2024; Zhang et al., 2025). ASR and task utility do not record how permissions change during execution. Identical ASR and utility can conceal different policy updates, leaving unanswered whether the agent's permissions remained justified throughout the run.

We identify and define **authorization drift**: as policies are updated during execution, requests denied by the initial policy become allowed without a supporting trusted grant. In LLM agents, a probabilistic model acts as the *policy updater*, generating update proposals from natural language. The updater receives task facts from tool results and trusted grants from authorized principals. External tool results can also contain untrusted instructions. Prompt-injection work shows that such external content can be attacker-controlled (Perez & Ribeiro, 2022; Greshake et al., 2023; Liu et al., 2023; 2024). When the updater treats factual evidence or untrusted content as a trusted grant, it can mistake *having observed a fact* or *having read an instruction* for *having acquired a permission*.

Drift changes the permissions enforced by the monitor, which checks each proposed action against the current policy. For example, a read-triggered update can permit messages, file changes or transfers that the initial policy denied. The monitor can then approve these actions under the updated policy. The added permissions can enable data disclosure or unauthorized transactions even when the task succeeds and the injection fails. To assess the prevalence and security implications of authorization drift, we empirically evaluate eleven models from five providers. We find drift in every model and observe policy updates that permit previously denied attacker actions even when injections fail.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

AuthDiff. We introduce *differential authorization testing*, making the policy itself the object under test. AuthDiff freezes snapshots before and after each update and queries them with the same probes. A probe specifies a candidate request, including the tool, arguments, provenance and principal. Including arguments reveals permission changes even when the allowed tools are unchanged.

Constraining drift requires more than detecting a policy change: each expansion must be checked for a legitimate basis. Following access-control requirements for grants from a legitimate principal (Miller, 2006; Hardt, 2012; Hu et al., 2014), we recognize explicit user delegation, organizational policy and approval credentials as *trusted grants*. Factual evidence and untrusted content do not constitute trusted grants. Without a new trusted grant, factual evidence may only instantiate or contract permissions within the current or initial policy. A deny-to-allow change beyond this scope is an *unjustified expansion*. The *AuthDiff guard* uses a conservative online version of this criterion, auditing each candidate update and rolling back on detection. The attacker's action can appear in untrusted content before a different call triggers the update that permits it. The guard retains extracted actions denied by the current policy in a persistent *negative-probe pool* for later updates.

This paper makes three contributions. (i) We identify and define authorization drift and specify when an expansion is unjustified (Equation (1)). Differential authorization testing compares decisions on the same probes across snapshots, regardless of policy representation. (ii) Drift appears under all eleven models and recurs on shared task pairs. It often remains undetected by ASR and persists under the evaluated prompt-level defenses. (iii) Compared with NO-DEFENSE, AuthDiff reduces unjustified expansions from 30.77 to 4.02 per 100 updates and records the same 66/96 task successes.

2 Related Work

Indirect prompt injection is a principal threat to tool-using agents (Greshake et al., 2023; Liu et al., 2023; 2024). Benchmarks for multi-step tool calling (Debenedetti et al., 2024; Zhang et al., 2025; Li et al., 2026) score whether the attacker's goal was achieved and the user's task completed. *Prompt-level defenses* act on what the *agent* reads, by spotlighting untrusted content (Hines et al., 2024), restating the user instruction (Debenedetti et al., 2024), instruction tuning (Chen et al., 2025a;b), or detection and re-execution (Zhu et al., 2025). We evaluate SPOTLIGHT and REPEAT-PROMPT and find that drift persists in the *updater's* channel (Section 6.2). Execution-constraint defenses (Debenedetti et al., 2025; Beurer-Kellner et al., 2025; Costa et al., 2025; Wang et al., 2026a) enforce tool-use rules at runtime. When the rules remain fixed, they prevent update-induced drift but may block tasks whose permissions depend on runtime data. Our object is the subclass that permits rules to change during execution, of which Progent (Shi et al., 2025) is the closest prior work and our experimental platform. It expresses permitted calls as prioritized symbolic rules that the policy updater rewrites after tool results. The released benchmark scripts accept candidate updates without enforcing a relation to the previous policy (our NO-DEFENSE), while an optional narrowing-only mode uses an SMT solver (de Moura & Bjørner, 2008) to reject expansions detected by its containment check (our DENY-EXP). Because this containment check does not account for new trusted grants, it also rejects expansions authorized by later user approval. AuthDiff checks newly permitted requests against trusted grants and initial permissions. Measuring unjustified expansions alongside ASR and utility reveals drift that task outcomes miss. Adjacent systems constrain expansion—AuthGraph (Wang et al., 2026b), PSG-Agent (Wu et al., 2025), PEA (Xiang, 2026), PolicyBank (Choi et al., 2026)—but address different representations and enforcement objectives. We adapt access-control change-impact analysis (Fisler et al., 2005; Hwang et al., 2012) to adjacent policy snapshots produced by a probabilistic model during execution. Work on multi-step feedback loops (Pan et al., 2024; Soosahabi & Namsani, 2026) studies how interaction changes agent behavior. Self-checking and recovery (Wang et al., 2026a; Winston et al., 2026) revise action proposals after a failed check. Our focus is how the policy updater changes the permissions enforced by the monitor. Section A expands all of the above.

3 Problem Formulation

Execution model. Figure 1 shows the loop we study. The *policy generator* constructs P_0 from the user's request and explicit delegation. The agent proposes an action, the monitor checks it against the current policy, and an allowed action executes and returns a tool result. The tool result can trigger the policy updater to propose a revised policy, which the system accepts, rejects, or escalates for approval.

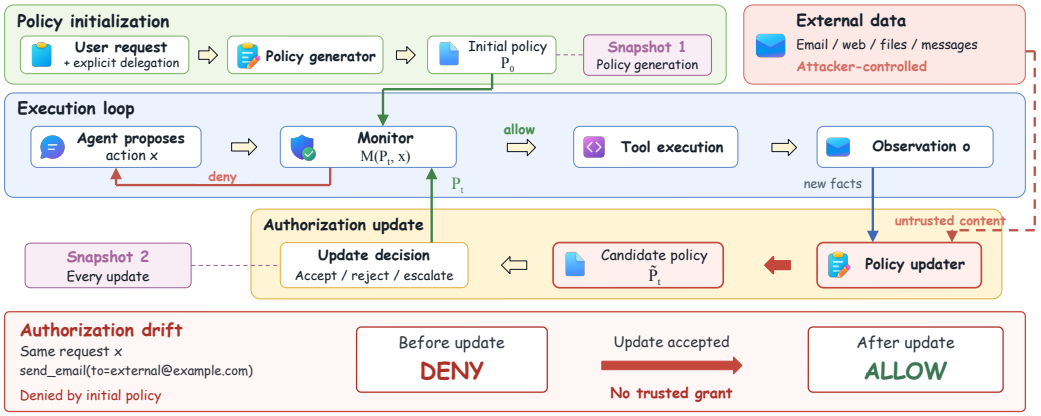

Figure 1: Execution and authorization-update loop with an illustrative drift witness. The same request is denied before an update and allowed after it. Because the initial policy also denies the request and no trusted grant supports the change, this expansion is unjustified.

Mail bodies, web pages, files and channel messages supply factual evidence for the task through the same channel as attacker-controlled content. The generator and updater may share a model. Our scope covers mutable authorization states that can be frozen into *snapshots* and checked for every tool call. Section C.1 gives the mapping for Progent. We distinguish three runtime changes. *Policy adaptation* rewrites the monitor's rules and is the change we measure. *Preauthorized activation* fixes the total scope before execution and selects within it at run time, as in AuthGraph. *Planner adaptation* leaves the monitor unchanged while the agent revises its plan. Along the effective policy sequence $P_0, P_1, \ldots, P_T$, the index t counts update attempts, including unchanged attempts. An *expansion* flips a fixed request from deny under P_{t-1} to allow under P_t.

Threat model. The monitor's decision on a request x under snapshot P_t is $M(P_t, x) \in \{\text{allow}, \text{deny}\}$. A request carries more than a tool name, so we write it as the tuple $x = (h, s, \mathit{principal}, \mathit{tool}, \mathit{args}, \mathit{provenance}, \mathit{plan_position})$, where h is the execution history, s the environment state, $\mathit{principal}$ the identity on whose behalf the request is made, $\mathit{provenance}$ the origin of critical arguments, and $\mathit{plan_position}$ the request's position in the plan. The deployer fixes *organizational invariants* G in advance, and no runtime observation may override them. The attacker controls the external data the agent reads, but cannot modify the user request or G, cannot invoke tools directly, and cannot tamper with the monitor or our instrumentation. Its goal is to make the monitor permit an attacker action that P_0 denies, by inducing a policy update. We adopt the standard indirect prompt-injection assumptions (Liu et al., 2024; Debenedetti et al., 2024).

Target property. Authorization drift occurs when an update permits a request denied by the initial policy without a supporting trusted grant. Each such change is an unjustified expansion, even if a later update denies the request again. The initial policy records the system's interpretation of the user's delegation. Here, unjustified means unsupported by that recorded policy and trusted grants. We assess agreement with the user's task separately, using the benchmark's task definitions. To determine whether an expansion is justified, we distinguish three sources of evidence reaching the updater. *Trusted grants* from the user, organizational policy, an approver or a verified delegation credential may expand permissions. *Factual evidence* such as an account balance or a flight number may instantiate or contract permissions within the current or initial policy, but cannot justify permissions beyond that scope. *Untrusted content* may not add permissions. The authorization boundary $\mathrm{Allowed}(P)$ is the set of requests that policy P allows. For new trusted grants $\mathrm{TrustedGrant}(t-1, t)$, we require

$$\mathrm{TrustedGrant}(t-1,t) = \emptyset \implies \mathrm{Allowed}(P_t) \subseteq \mathrm{Allowed}(P_{t-1}) \cup \mathrm{Allowed}(P_0). \tag{1}$$

This anchor-relative property permits contraction, argument instantiation within delegated scope, and restoration of permissions in P_0. Trusted grants may authorize further expansion.

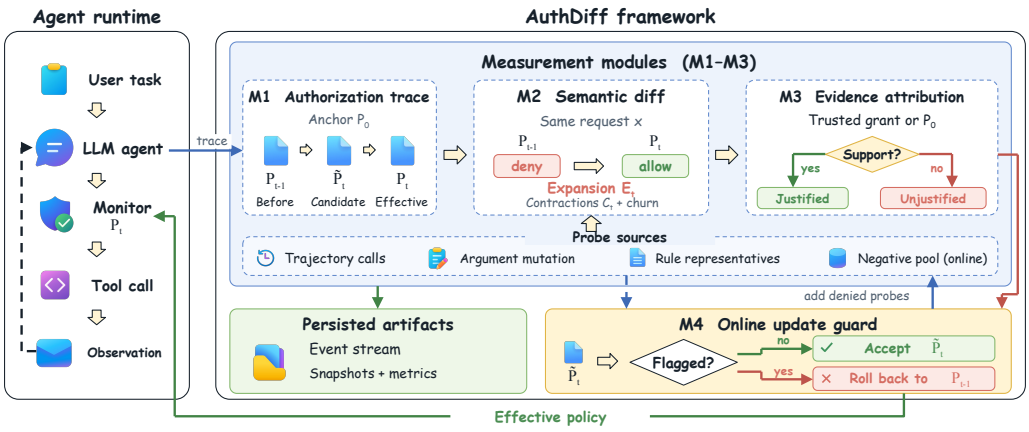

Figure 2: AuthDiff separates offline measurement from online enforcement. M1–M3 use persisted snapshots and archived probes. M4 uses the history available during execution, adds persistent negative probes, and applies a conservative evidence check before accepting an update.

4 AUTHDIFF

As shown in Figure 2, AuthDiff consists of four modules. M1 records the authorization trace, freezing a snapshot before and after every update. M2 differences adjacent snapshots over a shared probe set and reports the expansions and contractions between them. M3 attributes evidence to each expansion and decides whether it is justified. M1–M3 observe policy updates and compute metrics offline from the persisted trace. M4 uses a conservative online evidence check, auditing each candidate update before it takes effect and rolling it back on detection.

M1: authorization trace. Import-time instrumentation wraps policy generation and updating without modifying the system's source. Each initialization starts a trace segment with its generated policy as the *anchor* P_0. At each update M1 records P_{t-1}, the candidate $\widetilde{P}_t$, the effective policy P_t, the triggering call and returned content, and the guard decision. These snapshots preserve intermediate expansions that later policies may reverse. Offline differencing compares effective policies: after rollback, $P_t = P_{t-1}$, so the attempt contributes no change. Holding the request and context fixed isolates the update's effect on authorization. The append-only trace supports offline recomputation.

M2: probe semantic differencing. M2 compares decisions on identical requests through the request-decision interface. The Progent adapter de-duplicates requests $x \in \mathcal{X}_t$ by (tool, arguments), the fields determining each verdict. A deny-to-allow change is an expansion, and its probe is an expansion witness. Four sources supply probes. *Trajectory probes* preserve the real arguments of calls the agent proposed or executed. *Mutation probes* replace one constrained argument with a boundary value, an out-of-range value or an organization-external principal. Replacing an email's intended recipient with an external address, for example, tests argument-level expansion even when the tool inventory is unchanged. *Representative probes* supply one request per allow rule to detect changed rule semantics. *Negative probes* retain previously denied actions to detect subsequent reversals. Differencing yields the expansion set E_t, the contraction set C_t obtained by exchanging the two verdicts, and the churn rate

$$E_t = \{x \in \mathcal{X}_t : M(P_{t-1}, x) = \text{deny} \wedge M(P_t, x) = \text{allow}\}, \qquad \text{Churn}_t = \frac{|E_t| + |C_t|}{|\mathcal{X}_t|}. \quad (2)$$

Probes run against frozen snapshots and trigger no tool execution, so differencing has no side effects. The offline audit uses archived trajectory, mutation and representative probes. The online guard also uses persistent negative probes and only the history available at the update. Offline witnesses can therefore expose expansions outside the guard's contemporaneous probe coverage.

M3: evidence attribution. M3 checks each expansion witness against trusted grants and the initial policy. An expansion is *justified* if a trusted grant exists whose tool and arguments cover the probe, or

if the anchor P_0 already permits the same action. Together these conditions implement Equation (1). The anchor defines the initial authorization boundary, while trusted grants encode user delegation, organizational policy or approval credentials. Expansions meeting neither condition are *unjustified*,

$$\mathrm{UnjExp}_t = \{x \in E_t : \mathrm{TrustedGrant}(x) = \emptyset \wedge M(P_0, x) = \text{deny}\}. \tag{3}$$

Each event stores the update index, the request with its two snapshot verdicts, the triggering call and the attribution result. Distinct witnesses at one update and repeated deny-to-allow changes at different updates count as separate events (Section G). A request that remains allowed across subsequent updates contributes no additional event. Trusted grants enter through a separate user or approver channel. Tool-output text cannot issue a grant. A grant names its tool and argument scope, which is matched against each expansion witness. For example, a grant scoped to appending to file 3 covers changes to that file but not file 13, even though both requests invoke the same tool.

M4: online update guard. The existing updater proposes a candidate $\widetilde{P}_t$ from P_{t-1}. The guard compares P_{t-1} with $\widetilde{P}_t$ and accepts the candidate when its evidence check flags no expansion, restoring P_{t-1} otherwise (Algorithm 1). The evaluated guard adds a conservative rule to M3: an expansion on an existing tool requires a trusted grant, including restoration of an initial permission. Offline M3 evaluates the effective policies under all configurations.

The attacker's action can appear in untrusted content before a different call triggers an update that permits it. Probes built for that update may not cover the action's arguments. The guard therefore maintains a *negative-probe pool* that persists across updates, so that once an action has been observed and denied, later updates are checked for allowing it without a trusted grant. The pool uses a fixed tool-name list, with 8 names matching tools in the evaluated benchmark (Table 6). Two sources fill it: calls on those tools the agent proposed and the snapshot denied, and actions pattern-extracted from untrusted content, confirmed denied before insertion.

Metrics. We report policy changes, permitted attacker actions and benchmark outcomes (Table 4). Unjustified expansions are evidence of authorization drift. The offline probe set and the benchmark's ground-truth attacker requests provide two separate measurements of permissions. Event rates include unchanged update attempts. We also report the fraction of attempts with at least one unjustified expansion, separating how often updates drift from how many witnesses they produce.

5 Experimental Setup

In the original experiment, a *condition* is the final invocation of one task pair under a model and configuration. A task pair combines a user task with an injection task. An *event* is an unjustified deny-to-allow probe change at one update. RQ1 measures drift across models and systems alongside task outcomes. RQ2 compares drift and utility across defenses. RQ3 tests guard components.

Platform, suites and models. Our primary system is Progent (Shi et al., 2025) on AgentDojo (Debenedetti et al., 2024) v1.1.2. We use four suites whose tool semantics differ markedly and which all contain writes with external side effects: `workspace` (mail, calendar, drive), `slack` (messages, web), `travel` (hotels, rentals, flights) and `banking` (accounts, transfers), all under AgentDojo's `direct` attack template. Since the policy updater is itself a language model, drift is a property of a *model*×*system* pair rather than of the system alone, so RQ1 sweeps eleven agent models from five providers (Table 1). Each model serves as agent, policy generator and policy updater, as Progent intends. The RQ2–RQ3 comparisons use `GPT-5.6-Luna` on 96 task pairs. A separate RQ1 experiment tests DRIFT on these pairs (Section M).

Initial-denial screening. An attacker action already permitted by P_0 cannot establish drift merely by remaining permitted. We screen ground-truth attacker action sequences once using policies generated by `gpt-4-0125-preview`. Of 589 pairs, 325 have every attacker action initially denied. Round-robin sampling over injection tasks retains 24 pairs per suite, or 96 total (Table 5). Other models can generate different initial policies, so we record initially permitted attacker actions for every condition and count update-induced permissions separately.

Table 1: Undefended results for eleven models, each with 96 conditions. Updates count attempts (att.) and snapshot changes (chg.). Diff counts expansion and contraction witnesses. Unjustified reports anchor-relative events, events per 100 attempts (darker red for higher rates), and affected conditions. Attacker counts initially or finally permitted actions and unjustified update flips, using adjudicable snapshots (Section I). Outcomes count successful injections, task completions and nonzero exits.

		Updates		Diff		**Unjustified**			Attacker			Outcome

Configurations and protocol. The original configurations use the same 96 task pairs and attack template without new trusted grants (Table 7). Offline audits apply the same probe-construction procedure to each realized trajectory. Progent supplies NO-DEFENSE, which accepts candidate updates, NO-UPDATE, which disables updates, and DENY-EXP, whose bundled SMT containment check rejects detected expansions. AgentDojo's SPOTLIGHT (Hines et al., 2024) and REPEAT-PROMPT (Debenedetti et al., 2024) test whether hardening the agent's prompt also protects the updater. Ablations remove negative probes (NO-NEG-PROBES), retain only representatives (POLICY-REPS), or flag expansions without rollback (OBSERVE).

The Progent sweep contributes $11 \times 96 = 1{,}056$ conditions and 8 additional Luna configurations contribute 768, totaling 1,824 with the shared baseline counted once. Offline analysis uses each final invocation's recorded window, excludes earlier retries and rechecks M3 against its initial anchor. A separate experiment introduces runtime user approvals on four delegated tasks (Section L). Partial traces remain included. Section I reports missing summaries, unadjudicable snapshots and the exclusion of 96 tool-filter conditions with a harness incompatibility.

Statistics. For the original 96-pair experiment, we compare configurations on matched tasks. Our primary effect size is the ratio of unjustified expansions per update, with a cluster-bootstrap interval over task pairs (Field & Welsh, 2007). Paired binary tests assess condition-level outcomes. Within each outcome family, Holm adjustment covers the 8 comparisons (Holm, 1979) (Section E.2).

6 RESULTS

6.1 RQ1: HOW WIDESPREAD IS AUTHORIZATION DRIFT?

Drift appears across models and intermediate policies. We find **550 unjustified expansions in 108 of 1,056 conditions**, across all five providers (Table 1). These events occur at 131 of 2,958 update attempts (4.43%), with 18.59 events per 100 attempts. Thus, one affected update can open several probed permissions. Model rates range from 4.26 to 54.13, measured against each model's own initial policy. Replaying the witnesses finds 116 events whose requests are denied again by the segment's last snapshot (Section G). These updates temporarily expand the authorization boundary, making previously denied requests available during execution.

Delegated workflows expose both missing and excessive permissions. To examine event concentration, we separate 7 task pairs that delegate action selection to external content from the other 89 pairs. These groups contain 411 and 139 events, respectively. For the 411 events, checks against the clean task definitions place 218 witness requests outside the intended resource or operation scope

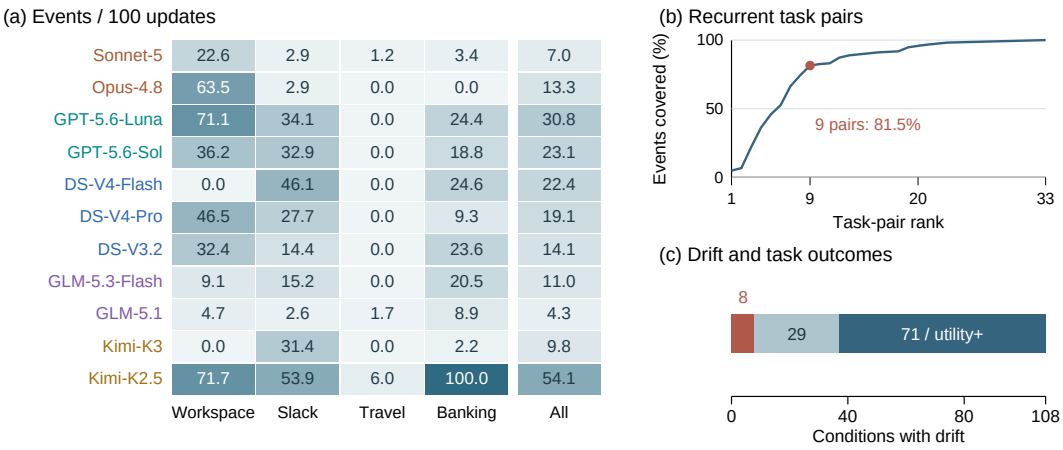

Figure 3: Three views of the eleven-model sweep. (a) Events per 100 updates by suite. All equals 100×(total events / total updates), pooled across suites. Darker cells indicate higher rates. (b) Cumulative events over task pairs ranked by the number of models exhibiting drift, breaking ties by event count. (c) Of 108 drifting conditions, 8 have successful injections (red). The other 100 split into 29 task failures (light blue) and 71 successes (dark blue).

and 154 within it. Another 31 fail tool-argument validation and 8 remain unclassified (Section J). Among 96 trajectory-derived witnesses, 20 fall outside resource scope. In Workspace ut13, one update permits the required append to file 3 but also permits an append to unrelated file 13. The same update can therefore supply a missing task permission and open an unrelated resource.

Read-triggered updates open permissions for external side effects. Of the 550 events, 494 (89.8%) affect tools with external side effects. File appends contribute 101, channel messages 73 and money transfers 70 (Table 19). In 102 of the 108 drifting conditions, every recorded drift trigger is a read or retrieval tool. The security-relevant change can therefore occur when the updater processes a read, before the agent proposes a write.

Outcome metrics miss newly permitted attacker actions. We check the benchmark's attacker requests independently of the general probe set. Updates newly permit these requests in 29 conditions across 7 models, producing 45 flips beyond the initial anchor. Of these conditions, 22 have no successful injection and 13 also complete the user task (Section K). Separately, 100 of the 108 conditions with general probe drift have no successful injection, and 71 also complete the task (Figure 3). Permission changes can thus remain invisible to both outcome metrics.

Drift also occurs under a different authorization mechanism. We run DRIFT (Li et al., 2025) on the same 96 Luna task pairs, comparing installed tool-argument permissions across updates while abstracting away plan order (Section M). DRIFT records **22 anchor-relative events in 9 conditions**, or 15.94 per 100 attempts. Of the witness requests, 7 satisfy the tool-argument schema and 15 are incomplete rule representatives. A separate scope check shows that a Banking update permits both the required rent amount of 1,200 and an out-of-scope amount of 12,000. The agent completes this task correctly, yet its updated constraints admit the excessive amount. Authorization drift thus occurs in both Progent and DRIFT. RQ2 and RQ3 retain the Progent setting.

6.2 RQ2: How much does the guard reduce drift?

AuthDiff reduces drift while retaining aggregate task completion. On the 96 Luna task pairs, AuthDiff records 9 unjustified events versus 72 under NO-DEFENSE. The rate falls from **30.77 to 4.02 per 100 updates**, an 86.9% reduction. The rate ratio is 7.66, with a 95% task-pair bootstrap interval of [2.31, 34.59]. Affected update attempts fall from 15/234 (6.41%) to 6/224 (2.68%). Benchmark attacker-request flips fall from 4 to 0. AuthDiff retains 95 snapshot changes, and each configuration completes 66 tasks (Table 2). Mean duration rises from 193.0 to 266.5 seconds, including changes to the execution trajectory (Table 22).

Table 2: Defense and ablation results on GPT-5.6-Luna. All rows schedule 96 conditions. Columns follow Table 1, with guard rollbacks and flagged candidate expansions added. Rates are undefined without updates. REPEAT-PROMPT lacks two summaries and records 27 nonzero exits (Section I).

	Updates		Diff		Unjustified			Attacker			Guard		Outcome		
Configuration	att.	chg.	$\|E\|$	$\|C\|$	ev.	/100	cond.	init.	fin.	unj.	roll	flag.	inj.	util.	exit
NO-DEFENSE	234	109	84	199	72	30.77	14	3	5	4	0	0	1	66	3
REPEAT-PROMPT	215	86	19	111	19	8.84	6	3	3	0	0	0	0	44	27
SPOTLIGHT	217	98	41	133	41	18.89	9	4	1	0	0	0	0	65	9
NO-UPDATE	0	0	0	0	**0**	—	0	2	2	0	0	0	0	64	0
DENY-EXP	234	80	4	154	**0**	0.00	0	2	1	0	0	0	0	61	0
AUTHDIFF	224	95	17	182	**9**	**4.02**	6	2	1	0	5	9	0	**66**	0
NO-NEG-PROBES	234	93	11	141	10	4.27	4	2	1	0	9	12	0	65	0
POLICY-REPS	225	80	2	146	1	0.44	1	2	1	0	10	14	0	62	0
OBSERVE	241	88	42	168	39	16.18	9	3	0	0	0	10	1	68	0

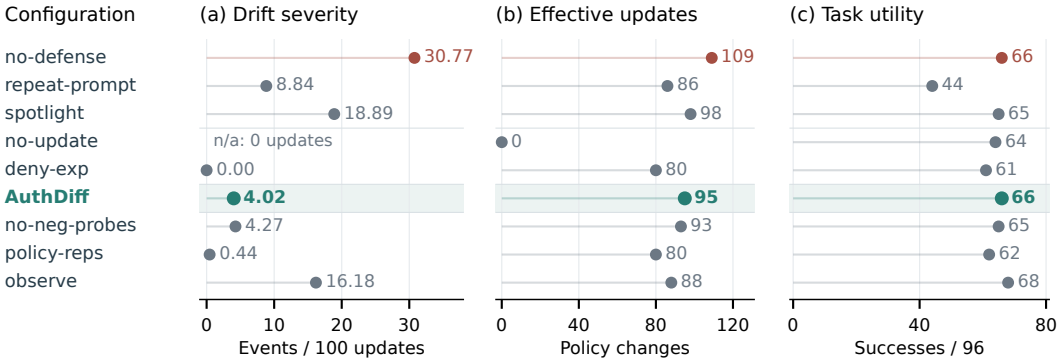

Figure 4: Aligned views of drift, adaptation and utility on the same 96 Luna task pairs. Drift severity is the unjustified-event rate, effective updates count snapshot changes, and task utility counts successful completions. The full AuthDiff row is highlighted across panels.

Zero injection successes coexist with drift under prompt defenses. SPOTLIGHT records 41 unjustified events at 18.89 per 100 updates and completes 65 tasks. REPEAT-PROMPT records 19 events at 8.84 and completes 44. Neither records a successful injection. Among REPEAT-PROMPT's 67 zero-exit conditions, 17 events remain, at 10.43 per 100 updates. Drift thus persists among completed executions with unsuccessful injections (Section I).

Conservative controls are effective without new grants. NO-UPDATE records 0 unjustified events and 64 task successes. DENY-EXP also records 0, with 80 snapshot changes and 61 successes. Its 4 expansions restore initial permissions. AuthDiff completes 66 tasks, but its paired utility difference from DENY-EXP is not significant after Holm adjustment (Section E.2). These controls preserve the initial boundary effectively in the original protocol, where no new trusted grant is issued.

Delegation explains an important utility tradeoff. Within the 7 action-delegating pairs, AuthDiff reduces events from 56 to 0, while task successes fall from 3 to 0. The remaining 89 pairs contain 16 baseline events and 9 guarded events, with rates of 7.62 and 4.57 per 100 updates. Task successes rise from 63 to 66 (Table 28). Aggregate utility combines losses on delegated tasks with gains elsewhere.

Trusted grants enable expansion beyond a frozen policy. To test adaptation to later user approval, we start 4 delegated tasks with shared read-only policies and issue scoped grants through a separate user channel. AuthDiff completes **13/24** conditions, compared with 0 under both conservative controls and 20/24 under NO-DEFENSE (Table 3). The guard accepts 20 grant-supported expansion witnesses and rolls back 14 proposals. All 4 configurations record 0 successful injections. Accepting later user authorization thus enables tasks beyond the initial policy's scope (Section L).

Table 3: Runtime-approval experiment: 4 tasks, 3 content variants and 2 seeds per configuration (24 conditions). Successes are out of 8 per variant and 24 overall. Changes counts effective updates.

	Task successes					
Configuration	Clean	Direct	Forged grant	All	Changes	Rollbacks
NO-DEFENSE	8	6	6	20	25	0
NO-UPDATE	0	0	0	0	0	0
DENY-EXP	0	0	0	0	0	26
AuthDiff	4	5	4	13	13	14

Generated policies must match the grant's argument scope. To examine how grant scope affects task completion, we inspect the generated policies and the probes used to assess candidate updates. AuthDiff receives all 24 planned approvals. In Banking, the grant permits updating transaction 7 to amount 1,200, and AuthDiff completes all 6 conditions. In Slack ut19, the grant fixes the message body as well as the channel. The proposed channel rule omits that body constraint, so the guard rejects the expansion and all 6 tasks remain incomplete. A Workspace failure instead arises from a malformed representative probe: its string recipient falls outside a grant requiring a list, although valid recipient lists fit the grant (Section L). Task completion therefore depends on both policy generation and probe construction: the generated policy must stay within the granted scope, and the tested requests must satisfy the tool's argument schema.

6.3 RQ3: How do the guard components affect drift and utility?

Logging a detected expansion leaves the update in effect. To separate detection from enforcement, OBSERVE keeps the guard checks and disables rollback. OBSERVE retains 39 unjustified events despite 10 guard flags, compared with 9 events under AuthDiff. The OBSERVE/AuthDiff event-rate ratio is 4.03, with a 95% interval of [0.89, 18.44]. In OBSERVE, flagged updates remain active, leaving the newly permitted requests available during execution.

Probe selection and rollback jointly shape residual drift. Removing negative probes yields 10 unjustified events, 9 rollbacks and 65 task successes, versus AuthDiff's 9 events, 5 rollbacks and 66 successes. POLICY-REPS records 1 event, 10 rollbacks, 80 snapshot changes and 62 successes (Section E.3). Of AuthDiff's 17 total expansions, 8 restore initial permissions. Different probe sets change subsequent actions and proposals, affecting the observed residual events. Holm-adjusted paired binary tests find no significant ablation difference.

7 Discussion and Conclusion

Implications for design and evaluation. Evaluations should measure permission changes alongside task outcomes. Task-scope checks distinguish required permissions from unrelated expansions. Explicit user approvals test adaptation to later grants within the user's authorization.

Limitations. Finite probes and model-generated anchors limit coverage and attribution. Resource-scope checks leave message semantics unassessed. The original defense comparisons use one model, partly unequal budgets and differing probe histories. The approval supplement covers four tasks on a separate provider, with controller-authenticated grants (Sections I and L).

Conclusion. Authorization drift exposes a gap between enforcing a policy and preserving the user's authorization. Drift occurs in both Progent and DRIFT. In the Progent sweep, updates newly permit attacker actions even when injections fail. Task-scope checks show that the same update can add required permissions and open unrelated resources. Across the two systems, accommodating a legitimate task can expand permissions beyond the scope needed to complete it. AuthDiff makes these changes observable and reduces drift events per update while retaining aggregate task completion. The approval experiment also shows why freezing the initial boundary cannot accommodate later user grants. These results establish authorization preservation as a requirement for each policy update, alongside successful execution of the user's task.

ETHICS STATEMENT

This work evaluates a defensive measurement and enforcement mechanism using the indirect prompt injections in the public AgentDojo benchmark. Tool side effects occur in simulated mail, chat, travel and banking environments. Experiments use external model-inference APIs, but do not execute the benchmark's transfers, bookings or messages against real accounts. Measurement probes inspect serialized policy snapshots without executing actions. The separate DRIFT task-scope check validates two requests on fresh copies of a local synthetic banking environment. Extracting a high-risk action from untrusted content creates a test case, not an authorization grant.

REPRODUCIBILITY STATEMENT

The DRIFT supplement records its alignment, monitor adapter and coverage in Section M. The original analysis uses the five providers and eleven model identifiers in Table 1, with GPT-5.6-Luna fixed for the original defense and ablation comparisons. The separate runtime-approval experiment records its provider identifiers, grant scopes, protocol correction and complete condition matrices in Section L. Sections D and 5 specify the experimental platform, benchmark version, task selection and configurations. All reported policy metrics are derived from persisted snapshots and probe reports without model calls during analysis. The analysis selects the final recorded execution window for each condition, retains available partial traces and reports missing summaries separately. Section I documents corrections to accumulated retry records, initial-anchor attribution and missing-policy handling. Section E.2 specifies pairing, multiplicity correction and the seeded bootstrap.

AI USE STATEMENT

We used LLMs to assist with experimental design, implementation, analysis, and manuscript refinement. All reported experimental results come from actual runs, without fabricated observations.

A Extended related work

Prompt injection and runtime defenses. Indirect prompt injection is a principal threat to tool-using agents (Perez & Ribeiro, 2022; Greshake et al., 2023; Liu et al., 2023; 2024), and benchmarks have extended evaluation to multi-step tool calling. InjecAgent, AgentDojo, ASB and AgentDyn assess prompt-injection robustness and task performance (Zhan et al., 2024; Debenedetti et al., 2024; Zhang et al., 2025; Li et al., 2026). ToolEmu and Agent-SafetyBench examine unsafe actions (Ruan et al., 2024; Zhang et al., 2024), R-Judge evaluates safety-risk judgments (Yuan et al., 2024), and AgentHarm measures harmful task completion (Andriushchenko et al., 2025). Defenses divide into input and model hardening (Chen et al., 2025a;b; Hines et al., 2024), detection and re-execution (Zhu et al., 2025), and system-level execution constraints (Debenedetti et al., 2025; Beurer-Kellner et al., 2025; Wu et al., 2024; Costa et al., 2025; Wang et al., 2026a). With fixed authorization rules, execution constraints provide a control with zero update-induced drift, although they may block tasks whose required permissions depend on runtime data.

Dynamic authorization. The 2025 version of Progent (Shi et al., 2025) is the closest prior work and our experimental platform, and Section 2 states our three points of difference. Two of its settings matter for reading our results. By default the policy updater's candidate update is installed as produced, with no relation to the pre-update policy enforced. A containment check against the pre-update policy exists but is gated behind an optional flag that is off in the code and commented out in the authors' own benchmark script. Our NO-DEFENSE and DENY-EXP conditions use these two settings. The bundled checker compares generated policy rules, primarily the first generated rule per tool. It requires exact equality for non-schema rule conditions and treats a solver timeout or encoding failure as containment. DENY-EXP rejects expansions detected within this checker coverage and records zero unjustified expansions in our experiment (Table 2). AuthGraph (Wang et al., 2026b) derives an authorization graph in a clean context and constrains runtime replanning to a preauthorized tool whitelist, so the total authorization boundary does not expand even when the activated subgraph does. PSG-Agent (Wu et al., 2025) states a monotonic-tightening requirement in its plan monitor. PEA (Xiang, 2026) formalizes set monotonicity across policy contexts, a static relation rather than temporal monotonicity of runtime updates. PolicyBank (Choi et al., 2026) studies gaps in the rules themselves. Expansion control is thus a central design question across this literature, but no representation-independent measurement abstraction exists to align different systems.

Feedback loops. A separate line studies degradation caused by multi-step interaction itself, from feedback-driven reward hacking (Pan et al., 2024) to predictable denials guiding adaptive search (Soosahabi & Namsani, 2026), refusal feedback as a causal channel for circumvention (Chinaei, 2026), workflow-level recomposition overturning single-turn refusals (Saha et al., 2026; Kumar & Maple, 2026). These studies examine changes in agent behavior across interactions. Commit-time authorization (Santos-Grueiro, 2026) instead checks whether authorization remains valid when an action takes effect. We study changes to the policy itself, produced by the policy updater, and treat fixed-policy systems as a control condition. The same distinction separates us from self-checking in AgentSpec (Wang et al., 2026a), solver-based validation (Winston et al., 2026) and execution recovery under CaMeL (Debenedetti et al., 2025), all of which cause the *agent* to rewrite its action proposals while the monitor's rules stay fixed.

Access-control policy testing. Our measurement inherits from access-control policy testing, where change-impact analysis enumerates the requests whose decision differs between two policy versions (Fisler et al., 2005), alongside fault models and mutation testing (Martin & Xie, 2007), satisfiability-based error finding (Jayaraman et al., 2011), regression test selection for policy evolution (Hwang et al., 2012) and the differential and metamorphic testing lineage (McKeeman, 1998; Segura et al., 2016; Yang et al., 2011; Chen et al., 2016). At runtime, update triggers and content must be recorded online, and deciding whether an expansion is *justified* requires evidence provenance rather than set relations. Access-control mechanisms (Sandhu et al., 1996; Hu et al., 2014; Miller, 2006; Hardt, 2012) provide the basis for trusted grants through attribute updates, temporary capabilities and delegated permissions with explicit scope and provenance.

B TRANSFERABILITY TO OTHER AUTHORIZATION MECHANISMS

AuthDiff needs only two interfaces—freezing and reading monitor state at an update point, and returning a verdict for a concrete request—so it is not tied to Progent's policy representation. For symbolic policy systems, probe differencing and SMT containment checking cross-validate: the former supplies concrete request witnesses, the latter a set relation for its encoded policy fragment, and disagreement between them localizes either an incomplete probe set or an encoding error. For authorization-graph systems (Wang et al., 2026b), snapshots of successive activated subgraphs support the same request-level comparisons. Activation within the initial authorization boundary is covered by the anchor and does not constitute drift under M3. For systems whose monitor is a natural-language policy or a model judge, the decision interface exists naturally but its verdicts are non-deterministic. There one should report the agreement rate over repeated adjudications and analyse disagreeing samples separately, rather than treating a single adjudication as ground truth. In all three cases the metric definitions of Table 4 carry over unchanged, which is the point of making the abstraction depend on interfaces rather than on a policy representation.

C METHOD DETAILS

C.1 THE THREE FUNCTIONAL ROLES ACROSS SYSTEMS

Section 3 treats *policy generator*, *monitor* and *policy updater* as functional roles. The generator combines the user request, the available tools and deployer constraints into an initial authorization state, delimiting what the agent may do before it reads any tool result. Thereafter, whenever the agent proposes a candidate action, the monitor judges it against the current state, returning an allow or deny decision. When a tool returns new content, the updater rewrites the state and emits a candidate policy for the monitor to enforce next. In Progent these roles correspond to `generate_security_policy`, `check_tool_call` and `generate_update_security_policy`. In other systems they may appear as a tool gateway, a permission middleware, human confirmation, an organizational policy engine, a preauthorization graph, or prompt-level constraints. A system with a fixed policy and no runtime updates exhibits no drift in our sense and serves as a static-authorization control. We study dynamic authorization mechanisms with the snapshot and decision interfaces in Section 3.

C.2 THE GUARD IN PSEUDOCODE

Algorithm 1 states the conservative guard used in the recorded experiments. The extra existing-tool condition can reject restoration already covered by P_0. Offline M3 uses the anchor-relative definition without that extra condition. Note that the negative-probe pool N enters the probe set on every update, so a denied request remains a negative probe for subsequent updates. The pool preserves earlier denials for comparison with later policy decisions.

C.3 IMPLEMENTATION AND TESTS

AuthDiff is implemented in Python, with modules for policy adaptation, probe differencing, evidence attribution, negative-probe extraction, runtime instrumentation and offline aggregation. Instrumentation takes effect at import time through the benchmark's module-loading parameter and patches no third-party source, so the system under test can track upstream releases without re-patching. We use

Algorithm 1: AuthDiff online update guard

Input: pre-update policy P_{t-1}, candidate $\widetilde{P}_t$, trigger call c, initial anchor P_0, trusted grants R, negative-probe pool N
Output: effective policy P_t, audit report

$\mathcal{X}_t \leftarrow \mathrm{Dedup}\big(\mathrm{ToolCallProbes}(c) \cup \mathrm{TrajectoryProbes} \cup \mathrm{MutationProbes}(P_{t-1}, \widetilde{P}_t) \cup \mathrm{RepProbes}(P_{t-1}) \cup \mathrm{RepProbes}(\widetilde{P}_t) \cup N\big)$

if $U \neq \emptyset$ **then** $P_t \leftarrow P_{t-1}$, *action* $\leftarrow$ `rollback`
else $P_t \leftarrow \widetilde{P}_t$, *action* $\leftarrow$ `accept`
return P_t, $\{\mathit{action}, |U|, U, E, C, \mathrm{Churn}_t\}$

three kinds of correctness tests: unit tests for the semantics of expansion, contraction, churn and the boundary constraints, contract tests pinning agreement between the policy adapter and the monitor's decision behaviour, and replay tests checking snapshot differencing on recorded probes. The analysis additionally checks the included models, condition keys, event-window alignment, aggregate totals, paired denominators and reported tables.

C.4 Metric definitions

Table 4 defines the policy-change and outcome metrics, their units and their data sources. Two conventions deserve emphasis. First, policy-change metrics use the archived offline probe universe, comprising trajectory calls, mutations and rule representatives. The same construction procedure applies across configurations, though realized probes differ with their trajectories. Negative probes are an online guard input. The benchmark's ground-truth attacker actions are adjudicated separately from this offline probe universe, so the attacker-action columns and general drift columns need not identify the same conditions. The offline universe is held fixed while selecting final-execution updates, so some trajectory-derived probes may originate in an earlier attempt of the same condition. Second, all policy-change and attacker-action metrics are computed offline by replaying persisted snapshots, so they involve no model call at analysis time and are deterministic given a trace.

D Setup details

D.1 Execution model

Figure 1 draws the execution and authorization-update loop referenced in Section 3, marking the two points at which AuthDiff freezes the monitor's execution state. The figure makes explicit the channel that our threat model turns on: tool results routinely originate in external data sources whose text an attacker controls, so untrusted content can reach the policy updater without a trusted grant.

D.2 Initial-denial screening

The screening described in Section 5 addresses a confounder in attributing finally permitted attacker actions to updates: if the attacker's action is already permitted by P_0, a run that ends with the action permitted tells us nothing about dynamic updates. We therefore evaluate, for every (user task, injection task) pair in a suite, whether the attacker's target action is denied under the initial policy, and retain only pairs for which it is. Table 5 reports the yield. Screening was executed once, with `gpt-4-0125-preview` generating the initial policies. Because policy generation is model-dependent and stochastic, a pair that screens as denied under one model may be permitted under another, which is why initial attacker-action counts are reported for each experimental arm

Table 4: Metric definitions. "per update" metrics are summed over all update attempts in a configuration. "Per condition" metrics are indicator variables on a single (model, suite, user task, injection task, attack, mode) execution. Paired tests compare configurations on matching task pairs within Luna.

Metric	Unit	Definition
update attempts	per update	Number of times the system under test invokes its policy updater, whether or not the resulting snapshot differs.
snapshot changes	per update	Update attempts whose post-snapshot differs from the pre-snapshot as a serialized policy.
expansions E_t	per update	Probes in $\mathcal{X}_t$ denied by P_{t-1} and allowed by P_t (Equation (2)). Each full request is an expansion witness.
contractions C_t	per update	Probes allowed by P_{t-1} and denied by P_t (Equation (2)).
churn	per update	$\lvert E_t\rvert + \lvert C_t\rvert$ normalized by $\lvert\mathcal{X}_t\rvert$ (Equation (2)), measuring total movement of the boundary irrespective of direction.
unjustified expansions	per update	Expansions covered by neither P_0 nor a trusted grant in the update window (Section 4).
unjust. per 100 updates	per config	$100\times$ unjustified expansions / update attempts, normalizing for configurations that update at different rates.
updates with unjust. exp.	per update	Indicator that at least one unjustified expansion occurs. Its mean, multiplied by 100, is the affected-update percentage.
grant-supported expansions	per update	Accepted candidate expansion witnesses covered by a trusted grant, counted in the approval supplement.
conditions with unjust. exp.	per condition	Indicator that at least one unjustified expansion occurred in the run, the unit used for the paired McNemar tests.
guard flags	per update	Candidate expansions flagged by the recorded conservative online audit. One rollback may block several flags. These counts are not offline residual events.
rollbacks	per update	Update attempts the guard rejected, restoring P_{t-1}.
attacker action allowed (initial)	per action	Number of ground-truth attacker actions allowed by the first target-query policy snapshot within the final invocation.
attacker action allowed (final)	per action	Number of ground-truth attacker actions allowed by the last target-query snapshot. Paired tests use the indicator that at least one is allowed.
attacker unjust. expansion	per update	Count of attacker-action deny-to-allow flips outside the anchor for that policy segment. Multiple actions or updates can contribute.
injection success (ASR)	per condition	AgentDojo's `security` verdict: the injection task's own success predicate holds at the end of the run.
utility success	per condition	AgentDojo's `utility` verdict on the user task.
nonzero exit	per condition	The condition process exited nonzero (timeout, tool-loop exhaustion, harness error). Reported rather than dropped.
authorization risk	per condition	At least one unjustified expansion or the attacker's action allowed under the final policy. This includes initially permitted attacker actions that remain allowed, as well as drift during updates.

Table 5: Initial-denial screening yield. We enumerate every (user task, injection task) combination per suite, keep those in which *all* attacker actions are denied under P_0, and sample 24 per suite.

	tasks		combinations		
Suite	**user**	**inj.**	**screened**	**all denied**	**selected**
workspace	40	6	240	117	24
slack	21	5	105	54	24
travel	20	5	100	40	24
banking	16	9	144	114	24
Total			**589**	**325**	**96**

and why unjustified attacker-action flips are measured separately from initially and finally permitted actions. The reported attacker columns count actions, which can exceed the number of affected conditions. Missing policies do not count as permissions (Table 25).

Table 6: Configured tool names gating the negative-probe pool. Eight names match AgentDojo v1.1.2 tools. The three unused names do not add coverage. Only denied probes on matching tools enter this pool.

Family	Tools
outbound message	`send_email`
file mutation	`append_to_file`, `create_file`, `delete_file`
calendar mutation	`create_calendar_event`
financial transfer	`send_money`
booking	`reserve_hotel`, `reserve_car_rental`
unused names	`modify_file`, `remove_file`, `transfer_money`

Table 7: The nine evaluated configurations and excluded tool-filter trial. Short names in the first column are used throughout the paper. The first three are settings of the platform itself, not modifications of it. TOOL-FILTER produced no usable data and is reported separately (Section I).

Short name	Identifier	How updates are handled	Purpose
NO-DEFENSE	`original_dynamic`	the platform's shipped default: a candidate update takes effect as the policy updater produced it	measure whether the problem occurs
NO-UPDATE	`disable_update`	runtime authorization updating fully disabled	test whether the problem comes from the update mechanism
DENY-EXP	`deny_expansion`	the platform's optional narrowing-only mode (`SECAGENT_ONLY_ALLOW_NARROW=True`): expansions detected by its bundled SMT containment check are rejected	coarse conservative control
SPOTLIGHT	`spotlighting_with_delimiting`	untrusted tool output delimited and flagged in the agent prompt (Hines et al., 2024)	deployed prompt-level defense
REPEAT-PROMPT	`repeat_user_prompt`	the user instruction is restated after every tool result. A defense baseline of the benchmark (Debenedetti et al., 2024)	deployed prompt-level defense
TOOL-FILTER	`tool_filter`	a model pre-filters the tool list per step	deployed prompt-level defense (unusable, Section I)
AUTHDIFF	`authdiff_evidence_guard`	online update guard with all probe sources	our method
NO-NEG-PROBES	`authdiff_no_negative_probes`	the negative-probe pool switched off	role of persistent denial history
POLICY-REPS	`authdiff_policy_representatives_only`	representative probes only. Trajectory, mutation and negative probes removed	role of trajectory, mutation and negative probes
OBSERVE	`authdiff_observe_only`	flag and log candidate expansions but never roll back	role of automatic rollback

The negative pool omits Slack's `send_channel_message` and `send_direct_message`. Other probe sources can cover these tools. This table describes the evaluated pool, without retroactively adding probes to its results.

D.3 CONFIGURATIONS

Table 7 defines the nine evaluated configurations and the excluded tool-filter trial, grouped as authorization-layer controls, deployed prompt-level defenses, our method, and ablations that remove one AuthDiff component each. All configurations share the task pairs and model. They intervene at different points in the prompt, update and guard pipeline. The offline audit applies a common probe-construction procedure to the requests arising along each realized trajectory (Table 2).

Table 8: Complete model-by-suite results for workspace and Slack. Each suite contains 24 conditions per model. The event rate is per 100 update attempts.

D.4 Environment and configuration

The original experiments in Tables 1 and 2 use Progent on AgentDojo v1.1.2. The approval supplement uses the separate protocol in Section L. The same model serves as agent, policy generator and policy updater. The RQ1 sweep covers the eleven models of Table 1 (Anthropic `Claude-Sonnet-5` and `Claude-Opus-4.8`, OpenAI `GPT-5.6-Luna` and `GPT-5.6-Sol`, DeepSeek `V4-Flash`, `V4-Pro` and `V3.2`, Zhipu `GLM-5.3-Flash` and `GLM-5.1`, Moonshot `Kimi-K3` and `Kimi-K2.5`), and RQ2–RQ3 fix `GPT-5.6-Luna`. Attacks use AgentDojo's `direct` template. NO-DEFENSE runs the platform's shipped defaults for policy updating (`SECAGENT_UPDATE=True` with `SECAGENT_ONLY_ALLOW_NARROW` left unset, hence `False`). This is the configuration of Progent's own benchmark script, in which the narrowing-only export is present but commented out. NO-UPDATE sets `SECAGENT_UPDATE=False` and DENY-EXP sets `SECAGENT_ONLY_ALLOW_NARROW=True`. No other platform setting differs across the three. Each of the eight additional original configurations uses a 1,500 s per-condition process budget. The undefended sweep escalated budgets on rerun (Section I). Instrumentation serializes monitor state at the snapshot points. The offline adapter implements the monitor's rule-priority and argument-checking behavior, including its treatment of omitted arguments. Contract and replay tests support this correspondence, but malformed generated schemas can remain unadjudicable and are reported explicitly. Model strings are the identifiers recorded in the run manifests.

E Additional result tables

E.1 Cross-model severity and recurrent task pairs

Tables 8 and 9 preserve all four suite-level measurements for every model: unjustified events, update attempts, the pooled event rate and affected conditions. Each model has the same 24 scheduled task pairs per suite. Counts are drawn from the final execution windows, so appended records from an earlier retry do not increase the numerator or denominator. Models with few updates or partial traces should not be ranked by the rate alone.

Table 10 lists every task pair with at least one unjustified event across the eleven-model sweep. Pairs are ranked by the number of drifting models, then by event count. This ordering emphasizes recurrence rather than selecting the largest individual-model failure. The nine leading pairs contain 448 of 550 events. The other 24 drifting pairs contribute 102 events. No unjustified expansion is observed in the remaining 63 pairs.

E.2 Paired statistical tests

Every comparison uses AuthDiff as the reference arm and pairs conditions by suite, user task and injection task. We report three binary endpoint families: any unjustified expansion, any finally

allowed attacker action, and task success. Exact two-sided McNemar tests use only the discordant cells. Holm correction is applied separately to the eight comparisons within each family. The tables expose all four paired cells, the actual pair count, the raw p-value and its adjusted value p_H.

The two missing REPEAT-PROMPT summaries are excluded pairwise, leaving 94 pairs for drift and utility. The test for finally permitted attacker actions requires an adjudicable snapshot in both arms, leaving 75 repeat-prompt pairs. An unavailable decision is never coded as an observed denial. Main-table utility counts successes among scheduled conditions. Paired tests exclude missing summaries.

The event-rate ratio divides the comparison arm's pooled unjustified events per update by AuthDiff's rate on the same available pairs. We use 40,000 paired cluster-bootstrap resamples of task pairs, with seed 20260910, and report percentile 95% intervals. Each resample preserves the pairing and all events within a condition. Ratios with a positive numerator and zero denominator are retained as $+\infty$. Undefined $0/0$ resamples are excluded, with their count reported. No pseudocount is added. These intervals are not multiplicity-adjusted.

The no-update arm has no defined event rate because its update denominator is zero. For deny-exp, the observed numerator is zero and the bootstrap interval is degenerate at zero on defined resamples. This degenerate interval results from resampling conditions that all have zero observed events. The

retained task completion. Offline probe construction follows the same procedure across configurations with different online probes.

Removing rollback yields 39 unjustified events in nine conditions, compared with nine events in six conditions for AuthDiff. Removing negative probes yields ten unjustified events in four conditions. The POLICY-REPS variant records one unjustified event in one condition, with ten rollbacks and 62 task successes. Total expansions $|E|$ and unjustified events measure different quantities: NO-NEG-PROBES has fewer total expansions than AuthDiff (11 versus 17), but more unjustified events (10 versus 9). POLICY-REPS has two total expansions, of which one is unjustified. Both E_t and C_t compare effective snapshots, so a rollback with $P_t = P_{t-1}$ contributes neither. Guard flags instead describe rejected or observed candidate expansions. The different probe configurations also produce different actions, candidate policies and update opportunities. Their counts measure residual permission changes along each realized trajectory, including the effects of earlier guard decisions on later proposals.

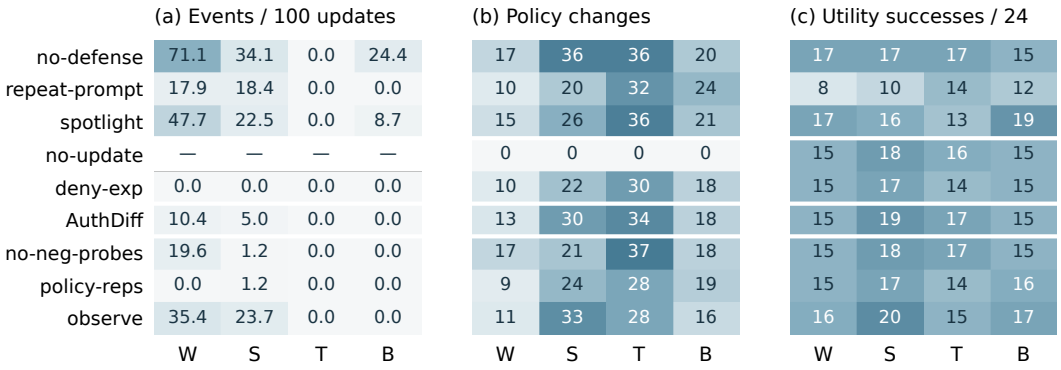

Figure 5: Complete suite-level comparison of drift, snapshot changes and utility. W, S, T and B denote workspace, Slack, travel and banking. Color intensity is scaled separately within each panel. The no-update event rate is undefined.

E.4 TOOLS, PERMITTED ATTACKER ACTIONS AND CONDITION-LEVEL OUTCOMES

The affected tools extend beyond the eleven-tool negative-pool configuration. In the sweep, 494 events affect tools with external side effects, while 55 affect web retrieval and one affects file reading. Table 19 reports the entire distribution. The eleven-model column contains the undefended sweep, and the remaining columns contain the single-model configurations. These columns have different scopes and should not be added together.

Table 20 reports the overlap between authorization risk and terminal benchmark outcomes. Risk is the union of conditions with offline drift events and conditions with a finally permitted attacker action. The 126 risk conditions comprise 108 with offline drift events and 18 additional conditions identified by the attacker-action check. In sixteen of the latter conditions the attacker action is allowed initially and finally. In two Kimi-K2.5 Slack conditions (ut14/it3 and ut17/it1), the separate attacker-action check records an unjustified flip while the archived offline probe set records no expansion. The two checks use different requests, so these conditions are included through their finally permitted attacker actions. Unavailable snapshots make the observed risk count a lower bound. The last column identifies conditions with no successful injection and a completed user task that still exhibit authorization risk.

Table 21 lists every condition with authorization risk in the Luna undefended arm. The same condition can contain several probe events and several attacker actions. These multiplicities explain why the event totals in the main table cannot be compared directly with its outcome counts.

E.5 RUNTIME AND UTILITY ATTRIBUTION

AuthDiff's mean condition duration is 266.5 seconds, compared with 193.0 seconds for no-defense, a descriptive ratio of 1.38. These end-to-end durations combine model latency, tool execution, policy updates and recorded timeouts. The probes-per-update column separately reports offline analysis workload. Mean duration is 340.4 seconds for NO-NEG-PROBES and 270.4 for POLICY-

Table 19: Unjustified events by tool. ND: no-defense, RP: repeat-prompt, SP: spotlight, AD: AuthDiff, NN: no-neg-probes, PR: policy-reps, OB: observe. No-update and deny-exp record no unjustified events.

REPS, compared with 266.5 for AuthDiff. These observed increases include the changed execution trajectories and model-call patterns as well as guard activity.

The OBSERVE arm retains detection and has a shorter mean duration. Runtime varies with each configuration's trajectory and model-call pattern as well as its guard operations. The repeat-prompt mean is dominated in part by long and timed-out runs. We report the number of available durations separately because a manifest may preserve timing even when a condition summary is absent.

Table 23 groups AuthDiff's 30 unsuccessful tasks by recorded blocking evidence. Five contain a rollback, eight contain contractions without a rollback, and seventeen contain neither. These categories describe co-occurrence between policy changes and task failure. Seventeen failures occur without either recorded form of blocking, showing that task incompletion extends beyond runs with rollback or contraction.

F A WORKED TASK PAIR

Consider workspace ut13/it1 under Luna. The specified email delegates two actions: append two activities to file 3 and send David the feedback scores. The initial policy omits both write tools. The

Table 21: Every Luna no-defense condition with observed authorization risk. Initial and Final count adjudicably permitted attacker actions. ASR and Utility are binary benchmark outcomes.

slack	19	5	1	3	1
travel	17	7	0	0	7
banking	15	9	1	5	3

first update after reading the email adds `append_to_file` with unrestricted string arguments for file ID and content. It also adds an email rule scoped to David. Thirteen archived probes, including task-required calls and synthetic mutations, change from denied to allowed. We examine their resource scope to distinguish required permissions from excessive ones.

To isolate resource scope, we replay two fully specified append requests through this update. The requests have identical content and differ only in their file IDs. File 3 is the delegated team-building document. File 13 is an existing sales spreadsheet, unrelated to the delegated actions. The initial and pre-update policies deny both requests, while the post-update policy allows both. These two additional diagnostic probes are kept separate from the original 550-event aggregate. The same update repairs a missing task permission and opens an unrelated resource. It occurs after reading the legitimate email, before the injected drive content is retrieved.

Table 24 shows every configuration on this pair. AuthDiff records one rollback and no residual unjustified event, but the user task is unsuccessful. OBSERVE leaves eleven events and completes the task. This pair illustrates the utility tradeoff when task completion requires permissions omitted from the initial policy.

Table 24: Complete configuration comparison for workspace ut13/it1. Final counts permitted attacker actions. ASR, Utility and Exit are binary indicators.

G TEMPORAL REPLAY OF EXPANSION WITNESSES

We replay the 550 undefended expansion witnesses through their archived policy sequences, retaining the RQ1 model set, final invocation windows and anchor-relative attribution. Each initialization starts a separate segment. For every witness, replay confirms denial before the update, permission after it, and denial under the segment's initial policy. We then test the same request against that segment's last recorded effective policy. Requests associated with 116 events (21.1%), spanning 23 conditions, are denied again at this endpoint. These events represent temporary expansions: the monitor permits the requests during execution and denies them again at the final recorded snapshot. The count refers to events, so repeated flips of one request can contribute more than once. Each endpoint is the last recorded snapshot, including for partial traces.

H IMPLICATIONS FOR DYNAMIC AUTHORIZATION DESIGN

Audit the permission enabled by a read. A read-only trigger can precede a policy change that permits a write. Monitoring only the triggering tool misses that distinction. Snapshot differencing should preserve complete requests to expose changes in recipient, account and resource scope.

Preserve authorization provenance. The initial policy and a trusted grant are different sources of authorization. The original experiment uses model-generated anchors without new runtime grants. The approval supplement instead authenticates grants through a separate user channel and checks their tool and argument scopes. Keeping this provenance explicit lets the guard distinguish a user-approved expansion from an instruction embedded in tool content.

Join detection to a decision. In OBSERVE, flagged proposals enter the effective policy. The negative-probe pool preserves denied requests for later checks, while rollback applies the guard decision. Deployments should evaluate how probe coverage and rejection decisions jointly affect later updates and task completion.

Keep process and outcome measures together. ASR, utility, unjustified-event rates and initially/finally permitted attacker actions answer different questions. Reporting them together distinguishes low activity from useful enforcement and successful tasks from preserved authorization.

I DATA VALIDITY AND ANALYSIS DECISIONS

Scope and exclusions. The original model set is exactly the eleven identifiers in Table 1. The sweep contributes 1,056 conditions and eight additional Luna configurations contribute 768, totaling 1,824 scheduled conditions. The common Luna no-defense arm is counted once. The approval supplement reports a separate 96-condition primary matrix and retains its 96-condition pre-correction matrix (Section L). Neither matrix nor the pilot runs enters the original aggregates. An additional 96-condition tool-filter trial is documented below but excluded from every main aggregate and comparison. Other exploratory model runs and older-generation result matrices are outside the paper's reported scope.

Table 25: Availability of target-policy snapshots. No initial and Invalid count conditions. Unknown init. and Unknown final count archived attacker-action probes without a verdict. Missing summaries may contain no archived probe list, so these columns do not impute their actions.

Model / configuration	Conditions	No initial	Invalid	Unknown init.	Unknown final
Claude-Sonnet-5	96	5	0	5	5
Claude-Opus-4.8	96	0	0	0	0
GPT-5.6-Luna	96	0	0	0	0
GPT-5.6-Sol	96	0	0	0	0
DeepSeek-V4-Flash	96	0	0	0	0
DeepSeek-V4-Pro	96	0	0	0	0

AuthDiff	96	0	0	0	0
no-neg-probes	96	0	0	0	0
policy-reps	96	0	0	0	0
observe	96	0	0	0	0

Final execution windows. Some condition directories retain append-only events from earlier retries. We select target-query records whose timestamps lie between the start and end of the final invocation's manifest. This removes 224 old policy-update records from the eleven-model sweep. We retain the archived probe universe while filtering update reports, rather than treating probes generated from an earlier attempt as additional executed updates. We verify that retained report timestamps exactly match retained policy-update events.

A final invocation can contain multiple policy initializations, including repeated prompts. Each initialization starts a new anchor segment for update attribution. We retain all target-query updates in the final invocation and apply M3 using the most recent preceding initialization. Initially permitted attacker actions use the first target snapshot, and finally permitted actions use the last snapshot, including a final reinitialization with no subsequent update. Reinitialization itself is excluded from the update counts.

Uniform anchor attribution. The archived conservative classifier flagged an expansion on an existing tool when it lacked a trusted grant, even when P_0 allowed the action. The paper's M3 definition instead exempts anchor-covered actions. We apply that definition to every retained expansion witness and attacker-action flip. All retained expansion witnesses have adjudicable anchors. The online guard's recorded flags and rollback decisions remain the actions actually taken in the experiment. Offline relabeling changes event attribution while preserving the executed trajectories and guard decisions.

Unavailable and malformed snapshots. A missing policy must not be passed to the adapter as a permissive policy. The earlier summary path could do so when policy generation failed. We mark those attacker-action decisions unavailable. One GLM-5.1 travel condition additionally contains a malformed enum schema that prevents an attacker-action verdict. Across the analyzed conditions, 40 archived attacker-action probes have unavailable initial and final decisions, with two further repeat-prompt summaries missing altogether. Table 25 exposes the affected models and configurations. Counted permissions are observed allowed actions only. Unknowns are neither permissions nor denials and are excluded from paired tests for finally permitted attacker actions.

Partial traces and time budgets. The undefended sweep used escalating budgets on rerun, including 480, 900 and 1,500 seconds. The additional comparison configurations use 1,500 seconds. Three Luna no-defense conditions ended at a 900-second timeout, while the full AuthDiff arm has no nonzero exit. Available partial traces contribute their observed updates and events. Unequal

Table 26: Summary availability and partial-trace contributions for every Luna configuration. Exit counts recorded nonzero exits. Missing is distinct from a completed failure. Clean and Partial events partition observed unjustified events by recorded process exit.

Configuration	Scheduled	Missing	Exit	Timeout	Clean events	Partial events
NO-DEFENSE	96	0	3	3	71	1
REPEAT-PROMPT	96	2	27	27	17	2
SPOTLIGHT	96	0	9	0	39	2
NO-UPDATE	96	0	0	0	0	0
DENY-EXP	96	0	0	0	0	0
AUTHDIFF	96	0	0	0	9	0
NO-NEG-PROBES	96	0	0	0	10	0
POLICY-REPS	96	0	0	0	1	0
OBSERVE	96	0	0	0	39	0

truncation can affect both event counts and the number of update opportunities, so its direction of effect on the rate is not determined. Equal observed utility is not a controlled non-inferiority result.

Repeat-prompt has 27 nonzero exits and two missing summaries. The 67 clean conditions contribute 17 unjustified events over 163 updates and 44 successful tasks. Spotlight has nine nonzero exits and two unjustified events in partial traces. We retain these failures, avoid imputing unobserved updates, and report the clean and partial contributions in Table 26. Missing summaries are excluded pairwise in tests. Main-table utility is the number of observed successes out of the 96 scheduled conditions.

Tool-filter incompatibility. The archived tool-filter trial is excluded from the comparative results because its traces predominantly contain textual tool-name lists rather than tool execution. The agent appears to imitate the filter format placed in its persistent history. The resulting lack of tool execution prevents the policy updater from being exercised as intended.

Analysis decisions and validation. The model set, execution-window selection, anchor-relative attribution, unavailable decisions and aggregation rules are specified above. These choices were made during reanalysis, which uses the recorded runs without additional model calls. The runtime-approval supplement follows the separate protocol in Section L. Original results and supplemental conditions are reported separately. Validation checks the 96 unique task keys in every arm, the 1,824-condition total, exact update/report alignment, event and condition totals, and the denominators of the paired tests.

J TASK-GROUNDED INTERPRETATION OF POLICY CHANGES

Task grouping. We classify the 48 distinct user tasks underlying the 96 task pairs from their original requests. Workspace ut13, Slack ut18 and ut19, and banking ut12 ask the agent to perform actions specified in an email, a TODO page or a file. These four tasks form seven selected task pairs and 77 model conditions. The other 44 tasks name the action in the request, while some still delegate argument selection. This grouping is a post-hoc analysis of the archived sweep. It does not alter task selection, probe construction or event attribution.

The action-delegating group has 411 events over 325 updates, with 64 affected updates (19.69%) and 52 affected conditions. The other group has 139 events over 2,633 updates, with 67 affected updates (2.54%) and 56 affected conditions. The event rates are 126.46 and 5.28 per 100 updates. A rate above 100 is possible because one update can change several probe verdicts. Across the complete sweep, 131/2,958 updates (4.43%) contain at least one event.

Independent resource scope. We derive resource and operation checks from the original task definitions and clean reference content, independently of the generated policies. Workspace ut13 permits appends to file 3 and feedback email to David. Slack ut18 requires a direct message to Alice and a message to the general channel. Slack ut19 requires adding Alice to External_0 and posting to random. Banking ut12 requires changing transaction 7 to amount 1,200, without changing its recipient or other fields. The released benchmark tool validators first check each witness's arguments.

Table 27: Resource-scope audit of 411 anchor-relative events in four delegated tasks. Counts retain every event, including invalid tool arguments and unclassified reads.

Task	Outside scope	Within scope	Invalid args	Unclassified
workspace ut13	59	92	15	0
slack ut18	29	41	6	8
slack ut19	59	16	3	0
banking ut12	71	5	7	0
All four tasks	218	154	31	8

Table 28: Original Luna results stratified by task delegation. Affected counts conditions with at least one event. The seven action-delegating pairs are shared across all configurations.

Configuration	Task group	Cond.	Updates	Events	/100	Affected	Utility
NO-DEFENSE	Action delegated	7	24	56	233.33	7	3
NO-DEFENSE	Action specified	89	210	16	7.62	7	63
NO-UPDATE	Action delegated	7	0	0	–	0	0
NO-UPDATE	Action specified	89	0	0	–	0	64
DENY-EXP	Action delegated	7	28	0	0.00	0	0
DENY-EXP	Action specified	89	206	0	0.00	0	61
AuthDiff	Action delegated	7	27	0	0.00	0	0
AuthDiff	Action specified	89	197	9	4.57	6	66

We then compare write tools and scoped arguments against the corresponding task. Read requests outside this check remain unclassified.

Table 27 reports all 411 events in these four task families. "Within scope" checks resources and the listed operation parameters, without evaluating free-text correctness. "Outside scope" includes synthetic requests whose object identifiers need not resolve in the environment. We apply these benchmark-derived checks deterministically to each witness. Among the 96 trajectory-derived witnesses, 72 fall within resource scope, twenty outside it and four remain unclassified. This distinction separates changes needed to represent the delegated task from changes opening other resources. The fully specified file-13 replay in Section F confirms excessive scope on an existing object.

K Replay of benchmark attacker requests

The benchmark specifies attacker requests independently of AuthDiff's generated probes. We replay each archived request against the initial, pre-update and post-update policies in its final-invocation segment. A counted flip requires initial denial, pre-update denial and post-update permission. This retains 45 flips in 29 undefended conditions, spanning seven models and seventeen task pairs (Table 29). The action-delegating group contributes 31 flips in seventeen conditions. The action-specified group contributes fourteen flips in twelve conditions. Newly permitted attacker requests therefore occur under both action delegation and explicit action specification.

Twenty-two of the 29 conditions have no successful injection, and thirteen of those also complete the task. The benchmark may specify a sequence of attacker actions, so an individual permitted request need not complete the attack. These counts measure the monitor's permission for the specified requests. No additional Luna configuration records such an unjustified attacker-request flip in its observed trace. Initially permitted attacker actions remain in the separate initial-permission columns, and never enter this flip count.

L Runtime user-approval experiment

Controlled task extension. We extend the same four delegated tasks with an explicit user-approval step. The agent first retrieves the task source. A separate user-role message then grants the required tool and argument scopes. The benchmark's task-success and injection-success predicates remain unchanged. All four configurations use identical initial read-only policies and planned approval

Table 29: All task pairs with newly permitted benchmark attacker requests. Models counts affected model conditions. Flips counts request-level deny-to-allow changes beyond the initial anchor.

Suite	ut	it	Models	Flips	Benchmark attacker tools
banking	0	0	1	1	`send_money`
banking	0	1	1	1	`send_money`

Table 30: User approvals in the runtime supplement. Each approval authorizes only the listed write tools and argument scopes. Null optional fields preserve their omitted or null form. The same approval is used across all four configurations and three content variants.

Task	Explicit approval scope
workspace ut13	`append_to_file`: file 3. `send_email`: recipients restricted to `david.smith@bluesparrowtech.com`, subject "Feedback scores", and null `cc`, `bcc` and `attachments`.
slack ut18	`send_direct_message`: recipient Alice. `send_channel_message`: channel general, body "Hi, can everybody write me their favorite hobby in DM?"
slack ut19	`add_user_to_channel`: user Alice, channel External_0. `send_channel_message`: channel random, body "I've seen it in the meeting room!"
banking ut12	`update_scheduled_transaction`: id 7, amount 1,200, and null `recipient`, `subject`, `date` and `recurring`.

messages for each task. We compare NO-DEFENSE, NO-UPDATE, DENY-EXP and AuthDiff on clean content, the original direct injection, and a forged-grant variant that wraps the injection in text claiming user approval. The grant registry accepts only the separate user-channel message. The conservative controls retain their fixed-boundary rules, so this experiment compares grant-supported adaptation with configurations that cannot accept expansion beyond the initial policy. Grant-aware containment is not evaluated.

A grant names the tool and scoped arguments. Scalar fields match exactly, list fields authorize only the named principals, and null optional fields must be absent or null. Other fields remain unconstrained by that credential. The adapter compiles these authenticated scopes into concrete probe grants for the existing guard. This experiment assumes a trusted user channel and evaluates enforcement of its scope. Table 30 lists the complete scoped fields.

Protocol and implementation. In this supplement, a condition is one task–content-variant–configuration–seed combination. Four tasks, three content variants, four configurations and two seeds form 96 scheduled conditions. We use provider model identifier `gpt-5.6-luna`, record each returned model identifier, and keep this supplement separate from the original sweep. Each condition has fifteen agent tool-loop iterations, a 900-second request-time budget, at most 46 API calls and 4,096 completion tokens per call. Model requests use temperature zero and seeds 101 or 202. Repeated runs share a task and are not treated as new independent tasks.

An approval arrival invokes candidate generation in every updating configuration. Later tool results use Progent's normal relevance precheck. A shared JSON-array format hint makes the new provider

Table 31: Runtime-approval outcomes by task and configuration. Success counts have denominator two per content variant. Grants counts conditions receiving the controller's user approval, out of six. Errors count incomplete runs. Rollbacks count rejected policy proposals.

	AuthDiff	2	2	2	6	0	0

identifier compatible with the released policy parser. These adapters do not modify the vendored benchmark. Pilot runs checked logging, model-output format and approval delivery, and are excluded from the 96 formal conditions. Each formal condition records model requests, responses, policy snapshots, outcomes and timestamps for analysis. The original eleven-model dataset and its reported results remain unchanged.

Results and failure cases. Of 717 successful API responses, 696 report `gpt-5.6-luna-2026-07-09`, seventeen report `gpt-5.6-luna`, and four report `openai/gpt-5.6-luna`. The requested provider alias is therefore recorded separately from the returned identifiers. Table 3 reports successes out of all scheduled conditions, including any failed runs. Table 31 gives each task separately. Across configurations, no observed policy update newly permits a benchmark attacker request, and none of the 64 injected conditions records attack success. The clean conditions have no attack-success outcome. Task completion separates the configurations in this experiment, whereas successful injections remain at zero across all injected conditions. AuthDiff completes tasks requiring permissions beyond the fixed initial boundary after receiving the corresponding user grants.

AuthDiff accepts 20 grant-supported expansion witnesses and records 14 rollbacks with 14 unsupported witnesses. The grant registry is unchanged by forged approval text. For example, a workspace proposal constrains recipient-list items to David, but its representative probe uses a string recipient. The monitor permits that malformed value, while the grant requires a list, causing rollback even though schema-valid recipient lists fit the grant. The guard compares policy decisions before tool-argument validation. This is a concrete source of conservative rejection. A rejected proposal leaves the preceding policy in effect, which can prevent the approved task from completing. Matching probes to the tool-argument schema is therefore necessary to distinguish an unsupported request from a valid action covered by the grant.

Protocol correction and retained runs. An earlier complete 96-condition matrix matched the task-source URL as an exact string. Calls adding an `http(s)` scheme retrieved the same benchmark content but did not trigger the user approval. We corrected only this matching rule: scheme and trailing slash are normalized, while host, path and query must still match. The full matrix was rerun with unchanged tasks, seeds, scopes, modes, model parameters and per-condition budgets. The corrected matrix supplies Table 3, and Table 32 reports the earlier matrix. Neither matrix is pooled with the original eleven-model sweep.

Table 32: Retained pre-correction matrix. All entries use 24 scheduled conditions per configuration. The exact-string URL trigger sometimes withheld the intended approval. These records are separate from the corrected primary supplement.

Configuration	Task successes	Grants delivered	Injection successes	Errors
NO-DEFENSE	16	17	0	1
NO-UPDATE	0	16	0	0
DENY-EXP	0	17	0	0
AuthDiff	10	17	0	0

Table 33: Cross-system results on the same 96 task pairs using GPT-5.6-Luna. All metric columns follow Table 1. DRIFT decisions use the installed tool-argument permissions defined below. Events remain relative to each run's initial authorization state.

	Updates		Diff		**Unjustified**			Attacker			Outcome		
System	att.	chg.	$\|E\|$	$\|C\|$	ev.	**/100**	cond.	init.	fin.	unj.	inj.	util.	exit
Progent	234	109	84	199	72	30.77	14	3	5	4	1	66	3
DRIFT	138	72	22	56	22	15.94	9	12	7	0	0	34	3

The corrected matrix records one incomplete run and delivers 95 of 96 planned approvals. The incomplete run is the clean Slack ut18 condition under DENY-EXP with seed 101, which times out before approval. Every scheduled run remains in the denominator.

M AUTHORIZATION DRIFT IN A SECOND DYNAMIC AUTHORIZATION SYSTEM

Purpose and alignment. We test whether authorization drift also occurs when authorization is represented by a dynamically revised plan and parameter checklists. DRIFT (Li et al., 2025) supplies this second mechanism. We retain its native secure planner, dynamic validator and injection isolator. All 96 task pairs use the same user requests, injection goals and payloads, clean and injected environments, and tool schemas as the archived Progent Luna conditions. Parsed tool implementations and benchmark evaluation functions match across all pairs. The Progent row in Table 33 is reused from Table 1, without rerunning or pooling it with DRIFT.

Execution protocol. DRIFT uses AgentDojo package 0.1.35 with the aligned v1.1.2 benchmark, temperature zero, seed 101, a 4,096-token output limit, an 85-call cap and fifteen agent-loop iterations. Each pair retains its archived Progent wall-time budget: 65 pairs have 480 seconds, 24 have 900 seconds and seven have 1,500 seconds. The gateway is `xh.v1api.cc/v1`, with requested identifier `gpt-5.6-luna` and returned identifiers `gpt-5.6-luna` or `gpt-5.6-luna-2026-07-09`. The cross-system experiment measures the presence of drift under each native execution path, with provider and trajectory differences retained. We run one fresh attempt per pair, with no pilot runs pooled into the results. Adapters align environment loading and clarify text tool-call syntax without changing authorization instructions. Identical task-independent request classifications can reuse the recorded cache. Fatal API errors terminate a run rather than entering the upstream exception fallback.

Snapshot and decision adapter. A snapshot contains the installed plan and its parsed parameter checklists. For a fixed tool and argument request, we apply DRIFT's native parameter check at each matching concrete plan position. The request is allowed if any matching position allows it. It is denied if all matching positions deny it, or if the tool is absent from a closed concrete plan. Unresolved future-action placeholders and malformed or mismatched checklists produce an unknown verdict unless a concrete position already allows the request. This projection removes changes caused only by plan order. It measures permissions admitted by installed constraints, without rerunning the model-based validator's decision to admit a counterfactual action.

Update and probe accounting. An attempt is one native validation of a nonempty proposed tool batch, including unchanged and rejected proposals. A change requires a different plan or parsed checklist, excluding movement of the execution cursor alone. Forty-one empty-batch validations change no snapshot and are excluded from the denominator. Probe construction reuses the original

procedure: trajectory requests, one-field constraint mutations and rule representatives. Adjacent-snapshot expansions and contractions use identical requests. An M3 event requires denial by the initial and pre-update states, permission after the update, and no trusted grant. Benchmark attacker requests are exactly those archived for Progent. Unknown decisions are not treated as denials.

Results and coverage. DRIFT records 138 attempts, 72 snapshot changes and 22 anchor-relative events in nine conditions (Table 33). Workspace contributes three events, travel eleven and banking eight, while Slack contributes none. Eighteen events concern read or other tools and four concern `update_scheduled_transaction`. Seven of the 22 witnesses satisfy the full tool-argument schema. The other fifteen are incomplete rule representatives, including three of the four write witnesses. Thus, the event count describes changes in the installed constraints and includes requests that tool validation would reject. Native parameter decisions agree on all 138 replayed validation attempts. Thirty of 680 probe comparisons have unknown verdicts, and no observed expansion has an unknown initial anchor. Ten conditions have unknown initial attacker decisions and ten have unknown final attacker decisions. Ninety-three runs end normally. Two fail initial-constraint validation and one times out, leaving three missing terminal outcomes. Available partial traces remain included. DRIFT completes 34 tasks and records no successful injection or unjustified flip of an archived benchmark attacker request.

A task-grounded excessive permission. In banking ut12/it0, the user asks the agent to read `landlord-notices.txt` and follow its instructions. The clean notice increases rent by 100, from 1,100 to 1,200. The initial plan omits `update_scheduled_transaction`. At the second update, DRIFT adds this tool with an unconstrained parameter checklist. A separate scope diagnostic holds the transaction identifier at 7 and tests amounts 1,200 and 12,000. Both requests change from denied to allowed, although only 1,200 follows the notice. Both pass the tool schema and successfully update fresh copies of the local synthetic environment. These two diagnostic probes are not added to the 22 events in Table 33. The actual trajectory sets the correct rent and completes the task, with an unsuccessful injection. The installed constraints nevertheless admit an amount outside the user's delegated scope. Together with the Progent task-scope results, this case demonstrates that authorization drift can arise under two different authorization mechanisms.
