SYNKER: SYNTHESIZE, KERNELIZE, REINFORCE — TEACHING GPU KERNEL GENERATION TO SMALL LANGUAGE MODELS

Anonymous authors
Paper under double-blind review

ABSTRACT

Combining test-time scaling with verifier execution feedback has demonstrated glimpses of frontier language models (LMs) being able to generate GPU kernels. However, small LMs still lack the capability to robustly produce compilable backend-specific code. We argue that this is largely due to a lack of diverse training environments and validated kernel datasets, representative of the target domain. To this end, we introduce SYNKER, a general recipe for improving LM kernel generation capabilities via synthetic task and solution generation: By evolving and translating natural-language task descriptions, we generate a large-scale set of diverse target operations. We then leverage evolutionary test-time search to generate an end-to-end validated kernel dataset across target backends. Finally, we use the resulting dataset to post-train open-source LMs of different families and scales using supervised fine-tuning and reinforcement learning. The resulting set of task environments contains 2,365 validated and configurable synthetic tasks and a kernel archive consisting of approximately 100k kernels across three backends. We demonstrate that the synthetic data enables effective post-training across a range of LMs. We further find that, under supervised fine-tuning (SFT), increased task diversity improves both validation performance and generalization to the held-out task, while the resulting SFT checkpoints provide better initializations for the subsequent reinforcement learning process. Together, these results indicate that SYNKER offers a practical and effective pipeline to improve the LMs kernel generation capabilities.

1 INTRODUCTION

Large language models (LLMs) increasingly write day-to-day software, but GPU kernel generation remains an unusually challenging setting. A candidate kernel proposal must not only match a reference operation over diverse inputs, but also avoid exploiting potential performance pitfalls like out-of-bounds accesses, incorrect memory usage, and reward hacking. Existing frontier models can produce correct kernel implementations when leveraging verifier feedback, but this capability drops significantly when considering small open-source language models. Closing this gap matters because the promise of low footprint, automated kernel engineering could enable new machine learning systems applications, such as online generation of kernels for specific hardware configurations and computation workloads. But training directly on existing fixed datasets or benchmark tasks (Ouyang et al., 2025; Lange et al., 2025b; Saroufim et al., 2025) risks narrow memorization rather than broad backend competence.

We argue that one crucial ingredient for making progress on this problem is the ability to autonomously generate a large-scale synthetic dataset of verified kernel implementations, which can then be used to teach and evaluate language model kernel generation capabilities. Our central hypothesis is simple: if the synthetic tasks are semantically diverse and the offline kernels are execution-verified, then post-training should improve generalization beyond the generator's original distribution. Hence, we treat kernel capability building as a task, data, and feedback co-evolution problem. Our proposed system, SYNKER, autonomously creates a diverse set of valid kernel generation tasks, searches for correct solutions using real execution feedback, and then distills the resulting strategies back into model weights. It operates in three sequential stages (Figure 1). First, SYNKER generates

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

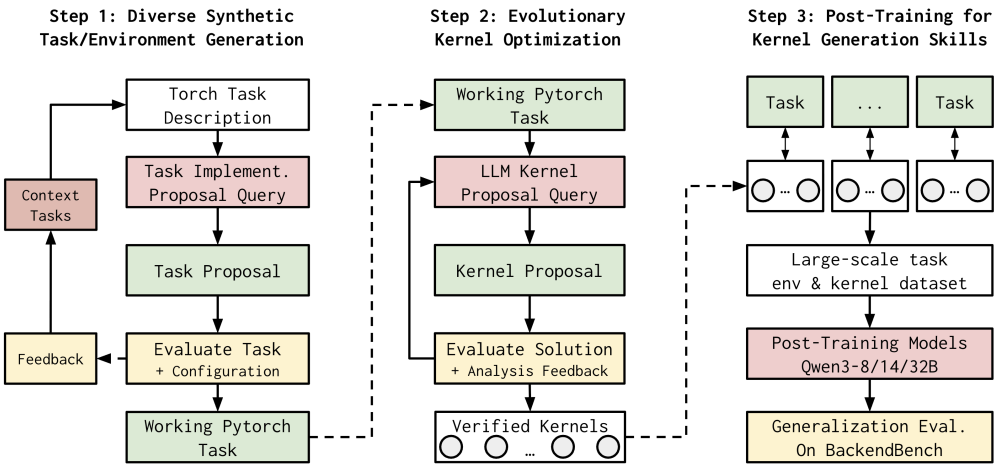

Figure 1: **Conceptual SYNKER pipeline.** *Left*: We generate validated synthetic kernel tasks by evolving natural-language task descriptions. *Middle:* We apply an evolutionary LLM-driven search for kernel translation and optimization across CUDA, Triton, and HIP. *Right*: The resulting kernel archive is used to train SLMs via SFT and RL, showing improvements with increasing task diversity.

synthetic task environments by evolving natural-language task descriptions and validating the resulting native PyTorch code. Second, we extend tree-based evolutionary test-time search methods (Lange et al., 2025a) to kernel translation and optimization across CUDA, Triton, and HIP. We apply this search procedure to each of the synthetic tasks to generate a large-scale dataset of verified kernel implementations. The resulting offline archive provides paired supervision between PyTorch tasks, generated kernels, measured outcomes, and feedback traces. Furthermore, each task comes with various kernel implementation strategies covering a diverse set of programming patterns. Afterwards, we use supervised fine-tuning (SFT) to distill the discovered kernel dataset into small language models (SLMs). Furthermore, we show that exploration through reinforcement learning (RL) and filtering can further improve kernel generation capabilities. This performance improvement is most pronounced after SFT. Our contributions are summarized as follows:

1. **Diverse synthetic task generation**: We build an autonomous task-generation pipeline that produces diverse and validated PyTorch operation environments based on LLM-driven task description evolution. The corpus contains 2,365 validated synthetic task environments. Each task can be instantiated with different input data and initialization configurations.
2. **Large-scale evolutionary test-time search**: We run code evolution over the synthetic tasks to create a verified archive of approximately 100,000 kernels across CUDA, Triton, and HIP. The procedure produces at least a single correct kernel for $\sim 70\%$ of the tasks and, on average, collects 20 kernels given a budget of $\sim \$0.5$ per task.
3. **SFT & RL for kernel generation**: We construct a curated PyTorch-to-kernel training corpus, and fine-tune different size models to improve held-out backend-generation performance measured by `BackendBench` (Saroufim et al., 2025). Additionally, we demonstrate the feasibility of RL fine-tuning of SLMs directly on the synthetic datasets.

2 RELATED WORK

Kernel-generation benchmarks. Recently multiple benchmarks have been proposed to assess LLM capabilities for kernel generation: First, `KernelBench` (Ouyang et al., 2025) introduced a set of 250 tasks across three complexity levels comprising basic linear algebra, neural network operations and entire architecture workflows. Subsequently, several works have demonstrated that some of the tasks in `KernelBench` suffer from evaluation loopholes that lead to reward hacking behavior, especially when measuring kernel runtimes (Lange et al., 2025b; METR, 2025). Follow-up benchmarks such as the GPU MODE competitions (Zhang et al., 2025) continually update mechanisms for preventing reward hacks, but are still vulnerable to advanced profiler hacks (Kokoromyti, 2026).

BackendBench (Saroufim et al., 2025) circumvents these issues by focusing on kernel *correctness* and replacing the original kernel generation tasks with a directly executable PyTorch backend implementation. Here, we focus on generating synthetic tasks with the sole purpose of being used for synthetic training data generation and rely on BackendBench for hold-out evaluation.

LLM code generation and agentic search. Modern code models can one-shot solve many programming tasks, but harder settings still benefit from execution feedback, profiling, and search (Chen et al., 2021; Li et al., 2022; Roziere et al., 2023; Hui et al., 2024; Zhu et al., 2024). In particular, difficult benchmarks such as SWE-bench (Jimenez et al., 2024) and ProgramBench (Yang et al., 2026) highlight the value of tool-use and tests for solving realistic code tasks. For GPU kernels, multi-turn and inference-time scaling methods that sample candidates, observe compile/runtime failures, and iterate have seen initial success on frontier models (Baronio et al., 2025; METR, 2025; Chen et al., 2025). SYNKER uses the same intuition, but turns search traces into post-training data for small, open-source models.

Evolutionary code optimization and open-ended task discovery. Recent LLM-based evolutionary systems combine language-model proposal distributions with automatic verification and selection (Romera-Paredes et al., 2024; Novikov et al., 2025; Lange et al., 2025a; 2024). Open-ended search also motivates synthetic task diversity: the task distribution itself becomes part of the capability-building loop (Lehman et al., 2023; Clune, 2019; Faldor et al., 2024; Zhang et al., 2024; Dai et al., 2026). Our task generation approach is closely inspired by Lu et al. (2025). Instead of generating synthetic tasks to evaluate frontier capabilities, we generate synthetic tasks in order to build a synthetic training dataset for post-training.

Datasets for specialization and post-training. Domain-specific fine-tuning depends on the abundance grounded data. Kernel data adds signals ordinary code that corpora rarely include: compile logs, correctness feedback, runtime information, backend labels, hardware context, and failed generation attempts. The largest currently publicly available kernel dataset, KernelBook (Paliskara & Saroufim, 2025), scraped existing PyTorch repositories from The Stack (Kocetkov et al., 2022), converted them to Triton using the TorchInductor compiler (Ansel et al., 2024). The SYNKER dataset is designed around these signals, with multiple verified kernels per task and cross-backend variants for shared PyTorch semantics.

3 SYNKER: TASK EVOLUTION, EVOLUTIONARY KERNEL SEARCH, AND POST-TRAINING

Next, we outline the three-stage SYNKER pipeline consisting of: (i) synthetic task generation, (ii) evolutionary kernel search that turns each task into correct, timed kernels across CUDA, Triton, and HIP, and (iii) post-training that distills the search results into a kernel-generation model.

Algorithm 1 Synthetic task generation

Input: prompt pool $\mathcal{P}$, LLM M, config sampler $\mathcal{C}$, budget N
$\mathcal{T} \leftarrow \emptyset$
for $i = 1$ **to** N **do**
  $p \leftarrow \textsc{EvolvePrompt}(\mathcal{P}, \mathcal{T})$
  $\tau \leftarrow M(p)$
  if $\neg\, \textsc{StaticOK}(\tau)$ **then**
    continue
  end if
  if $\neg\, \textsc{ExecOK}(\tau, \mathcal{C})$ **then**
    continue
  end if
  $\mathcal{T} \leftarrow \mathcal{T} \cup \{(\tau, \mathcal{C}_\tau)\}$
end for
Return: $\mathcal{T}$

Stage 1: Synthetic task generation SYNKER leverages an LLM-based evolutionary system for generating executable PyTorch task environments that can be executed. Each task environment describes a particular algorithm, and provides a mechanism for checking the correctness of an alternate implementation to the algorithm. In particular, it contains a reference implementation of the task, task metadata, and input/data initialization configurations. The generator starts with an initial seed task and evolves task descriptions via LLM mutation. Afterwards, an LLM proposes a PyTorch module-style implementation. The proposed code implementation is filtered

through static and execution checks (Alg. 1). Static checks reject malformed code, missing entry points, unsupported dependencies, and interface violations. Execution checks instantiate the task over the provided configurations and compare repeated outputs.

We use the diversity of the task name and description as a data-construction objective. The task generation process maintains a *task archive*, which begins with the *single* task seed: the Triangular Multiplicative Update module from AlphaFold2 (Jumper et al., 2021). We then alternates between task proposal and task generation. During task proposal, the system samples K tasks from the *task archive* with replacement and conditions an LLM proposer to mutate each task and generate a corresponding task description. An LLM judge then rejects proposals that are too similar to any other existing tasks in the archive. During the task generation phase, an LLM generates the code and test cases for each accepted proposal until it passes all static and execution code checks, with valid tasks being added to the archive. This process is repeated until enough tasks are generated. In Appendix A, we provide further details and prompts used at each step.

Stage 2: Evolutionary kernel optimization Given a validated task, SYNKER in parallel samples candidate LLMs from an ensemble and queries them to translate the PyTorch reference into CUDA, Triton, or HIP (Alg. 2). Afterwards, the responses are parsed, and their correct execution is attempted. CUDA/HIP candidates compile through `cpp_extension.load`; Triton candidates expose a Python `forward` that launches a `@triton.jit` kernel. We utilize the `robust-kbench` (Lange et al., 2025b) executor to run multi-input and multi-init correctness checks. Incorrect programs receive numerical, compiler, runtime, and optional LLM-summary feedback. Correct programs are timed against eager PyTorch and afterwards stored within a database. After having obtained an initial correct kernel, we follow the tree-based program optimization procedure of ShinkaEvolve (Lange et al., 2025a). The evolutionary search continues the search by sampling new candidate kernels that aim to improve the runtime, while exploring new algorithmic patterns and implementation motifs. This process is repeated until the budget is exhausted or a maximum API budget ($\$0.5$ per task including error summaries and verification checks) of kernel proposals is reached. More details are provided in Appendix B.

Algorithm 2 Evolutionary kernel search

Input: task τ, backend B, LLM M_B, budget N
$\mathcal{A} \leftarrow \emptyset$
for $i = 1$ **to** N **do**
  $k \leftarrow M_B(\tau, \mathcal{A})$
  $(\text{ok}_c, \ell_c) \leftarrow \textsc{Compile}_B(k)$
  if $\neg\, \text{ok}_c$ **then**
    $\textsc{Store}(k,\, 0,\, \ell_c)$
    continue
  end if
  $(\text{ok}_r, d) \leftarrow \textsc{Correct}(k, \tau)$
  if $\neg\, \text{ok}_r$ **then**
    $\textsc{Store}(k,\, 0)$
  else
    $s \leftarrow T(\tau_{\text{eager}})/T(k)$
    $\textsc{Store}(k, s)$
  end if
end for
Return: $\mathcal{A}$

SFT Dataset Construction: SYNKER converts the overall archive into supervised examples pairing a task prompt with a backend-specific kernel. For SFT, we only consider correct validated kernels and filter out all attempts without successful verification. Additionally, validation task identifiers are held out within each language. Each task later on can act as a reinforcement learning environment.

Stage 3: Post-training via SFT and RL We fine-tune Qwen3-family models (8B, 14B & 32B) and Gemma4-family dense model (12B, 31B) with LoRA adapters. All LoRA training setups use rank 8, $\alpha = 32$, bfloat16 training, AdamW with learning rate 5×10^{-5}, 5% warmup, effective global batch size 64, sequence length 4,000, and MS-SWIFT on 8 H100 GPUs, we sweep over {1,3} epochs and report results from the best-performing checkpoint. The diversity ablation fixes the kernel budget while varying distinct tasks. The cross-language ablation concatenates complete per-language pools. Evaluation uses held-out `BackendBench` tasks and reports compile success, correctness, and benchmark-specific pass metrics. We do not yet claim that the fine-tuned model improves the runtime performance of discovered kernels themself; The RL component's intended role is to bias outputs toward executable kernels. We use compilation and correctnes signals as filters or rewards. Because kernel rewards are sparse and hardware-dependent, the current draft presents RL dynamics as exploratory.

Table 1: Clustering of the 2,365 SYNKER synthetic tasks into thematic groups. For the largest 8 clusters, we report task counts, the percentage of tasks for which evolutionary search yields at least one correct kernel per backend, and the resulting number of kernels per backend.

			Solved tasks (%)			Shinka kernels			
#	Cluster	Tasks	CUDA	Triton	HIP	CUDA	Triton	HIP	Representative task function name
1	PDE, stencil, physics	164	71.34	73.17	68.29	3,460	2,883	2,478	`lbm_d2q9_step`

4 RESULTS: SYNTHETIC KERNEL TASK GENERATION

4.1 STEP 1: DIVERSE SYNTHETIC TASK GENERATION

The SYNKER pipeline issues iterative LLM proposals for new GPU-kernel tasks and filters each candidate through a cosine-similarity novelty gate on sentence embeddings of the task description. The left panel of Figure 2 shows how the number of accepted tasks accumulates as a function of the current number of generated tasks in the pipeline. Early proposals are accepted at a high rate; acceptance slows as the accepted set grows denser, and the curve flattens once the generator has difficulty producing descriptions that clear the novelty threshold. The resulting validated set contains **2,365 task environments** drawn from this diminishing-returns regime, ensuring that every accepted task adds meaningful semantic coverage rather than paraphrasing an existing one.

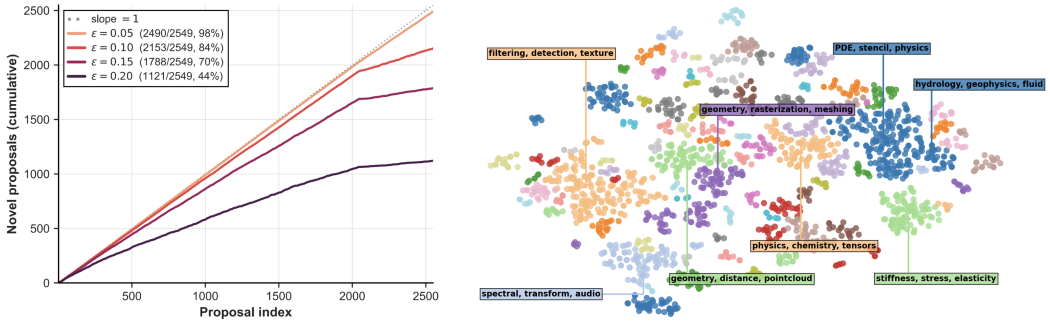

Figure 2: Diversity of the SYNKER synthetic task pool. **Left**: cumulative number of generated tasks whose embedding has cosine distance $\geq \varepsilon$ to all previously generated tasks, as a function of the number of currently verified tasks (which we denote as the Proposal Index), for several novelty thresholds ε on the L2-normalized task description embeddings. **Right**: 2D t-SNE projection of the task-description text embeddings, color-coded by DBSCAN cluster; labels mark the eight largest clusters that appear in Table 1.

The right panel of Figure 2 presents a 2D t-SNE projection of all task-description embeddings, colored by DBSCAN cluster. The projection reveals well-separated topical islands rather than a single dense mass, confirming that the novelty filter steers generation toward genuinely distinct problem domains. Table 1 quantifies this structure for the eight largest clusters, which together span a wide arc of scientific and engineering computing: numerical PDE and stencil methods (Cluster 1, 164 tasks), spectral and audio transforms (Cluster 3, 65 tasks), image filtering and texture analysis (Cluster 4, 131 tasks), molecular and continuum mechanics (Clusters 5 and 7), point-cloud and rasterization geometry (Clusters 6 and 8), and geophysical fluid dynamics (Cluster 2). The 2,365 tasks thus cover qualitatively distinct computational motifs, providing a broad substrate for the evolutionary search in Step 2 and ensuring that the resulting kernel corpus does not collapse onto a narrow slice of GPU programming patterns.

4.2 STEP 2: EVOLUTIONARY KERNEL OPTIMIZATION

Aggregate yield across backends. Across the 2,365 validated SYNKER tasks, evolutionary search recovers 38,407 correct CUDA kernels, 34,622 Triton kernels, and 32,660 HIP kernels, for a combined corpus of 105,689 correct (task, backend, kernel) triples (Table 1). Triton attains the highest solve rate (78.77% of tasks), followed by CUDA (69.56%) and HIP (65.37%). This ordering is consistent with the relative volume of each backend in public training data and with Triton's Python-first, tile-oriented surface area, which sits closer to the PyTorch reference than raw CUDA or HIP. CUDA nonetheless contributes the largest *absolute* kernel count: averaged over solved tasks, it yields roughly 23 correct kernels per task, versus $\sim$19 for Triton and $\sim$21 for HIP, indicating that once the search finds one correct CUDA implementation it tends to find many alternative phrasings of the same operator at a lower per-kernel API cost. HIP trails on solve rate but is competitive on per-task yield, consistent with weaker per-sample correctness rather than fewer search attempts.

Cluster-level structure. The Triton solve-rate lead holds across all eight clusters in Table 1, but its magnitude varies with task difficulty. Elementwise-heavy clusters (Clusters 2–4) achieve the highest absolute rates (82–84% Triton) with the smallest cross-backend spread, while Cluster 8 (*geometry, rasterization, meshing*) shows the widest gap: 74.5% Triton versus 54.9% on both CUDA and HIP. The remaining clusters occupy intermediate positions, with Triton consistently leading HIP by 8 to 19 percentage points.

Search dynamics and cost. Figure 3 (top) shows the per-cluster solve rate as a function of SYNKER generation for the four largest clusters. Most of the gain is realized in the first ten generations: by generation 10, every (cluster, backend) pair is within roughly five percentage points of its final solve rate, and the curves are essentially flat by generation 30. The cross-backend ordering Triton $\geq$ CUDA $>$ HIP is established within the first few generations and persists throughout the search.

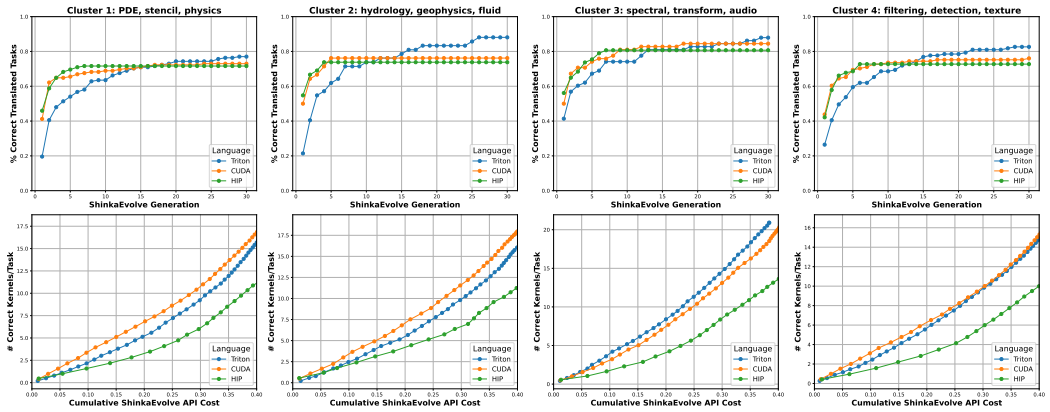

Figure 3: ShinkaEvolve search progress on the four largest task clusters by backend (CUDA, Triton, HIP). **Top**: fraction of tasks with at least one correct kernel as a function of ShinkaEvolve generation; the curves saturate within $\sim$30 generations for all clusters and backends. **Bottom**: average number of correct kernels per task as a function of cumulative ShinkaEvolve API cost, showing that further compute keeps producing additional correct solutions per task even after the solve rate plateaus.

Figure 3 (bottom) plots the average number of correct kernels per task against cumulative API cost. Unlike the solve rate, this quantity does *not* saturate: once the set of solvable tasks stops growing, additional spend continues to harvest new correct phrasings of already-solved tasks, reaching $\sim$17–20 correct kernels per task at the budgets we report. CUDA and Triton accumulate kernels at comparable rates per dollar; HIP grows more slowly, mirroring its lower per-sample correctness rather than a smaller sample budget. The SFT pipeline in Section 4.3 relies on this property: per-task correctness diversity, not just task coverage, is what determines the size and variety of the supervised corpus that downstream models are trained on.

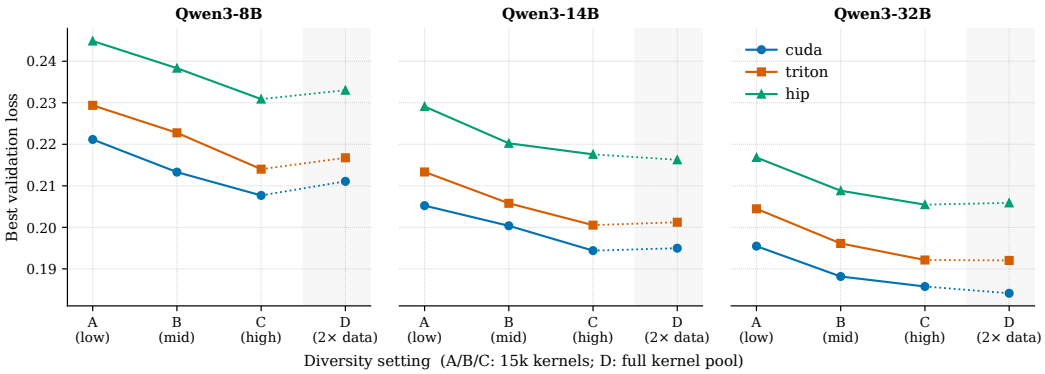

Figure 4: Best validation loss across the Qwen3 family (8B / 14B / 32B) on CUDA, Triton, and HIP under diversity tiers A–D. Shaded region and dotted segment mark tier D (full kernel pool). Across all model sizes and backends, more diverse tasks (A→C) lower validation loss.

4.3 Step 3: Post-training for Building Kernel Generation Capabilities

Source data and dataset split. All training and validation data are derived from our synthetic kernel corpus, the collection of (PyTorch task → GPU-kernel) pairs covering CUDA, HIP, and Triton. Within each language we hold out the last 200 task identifiers as a per-language validation pool, capped at 5 kernels per task. This yields 1k validation examples per language (CUDA 971, Triton 940, HIP 960), for stable validation-loss estimates. The remaining task identifiers (CUDA 1,345; Triton 1,754; HIP 1,443) form the training pool.

Model, training, and evaluation. We fine tune the Qwen3 family (8B, 14B and 32B) with LoRA (rank 8, $\alpha = 32$) on all linear projections in bfloat16, using AdamW with learning rate 5×10^{-5}, a 5% warmup ratio, an effective global batch size of 64, and a sequence length of 4,000. Training is run on 8 H100 GPUs. we sweep over 1, 3} epochs and select the best-performing checkpoint. This configuration follows a prior sweep over learning rate and batch size, and is held fixed across all runs for fair comparison; additional post-training details are in Appendix C.1. We evaluate on the full `BackendBench OpInfo` suite, comprising 271 bfloat16 ops. During the kernel generation, we follow the `BackendBench` recommended settings, temperature 0.2 and max output tokens of 16k. Each model-generated kernel is executed in a single-GPU subprocess, with a 600 second per-operator timeout. We report the PASS@1 metric: the fraction of the 271 ops for which the single sampled kernel passes all correctness test case checks. In addition to the Qwen3 experiments, we conduct SFT experiments on Gemma4 and report the corresponding validation losses. We observe trends consistent with those found for Qwen3, see Appendix C.3 for details.

Task-diversity study. We fix the kernel budget at 15k within each language and vary the number of distinct training tasks: tiers A, B, C use 50%, 75%, and 100% of the per-language task pool. Tier D keeps the same full task set as C but lifts the per-task cap and uses the full per-language kernel pool, separating the effect of kernel volume from the task diversity. Figure 4 reports the best validation loss across the Qwen3-8B/14B/32B family on all three backends. For each configuration, we sweep the number of training epochs in $\{1, 3\}$; all other hyperparameters follows Appendix C.2. Under the fixed budget, we find that validation loss decreases monotonically with diversity (A→B→C) for every (model, backend) pair, while the C→D step—doubling kernel volume without adding new tasks, produces no consistent improvement for the 8B model on CUDA, Triton, and HIP. This suggests that increasing training data volume without new diversity provides no reliable benefit. Moreover, the degradation attenuates with model scale: for both 14B and 32B models, at least one (model, backend) run shows improvement at the C→D step. The pattern holds across scales and backends, indicating that task diversity, not kernel volume, is the binding constraint for kernel-generation SFT.

The downstream BackendBench PASS@1 numbers in Figure 5 corroborate this on Triton. Relative to the un-tuned base models, tier C delivers the largest gains at every scale (7.74 / 8.42 / 10.44), while tier D fails to beat C at any size and collapses to 4.38 at 8B, mirroring the C→D regression in validation loss. We further observe a notable scale-dependent effect in tier A: the 8B model achieves

surprisingly strong results, outperforming what its size would suggest. Inspection of the training logs reveals that the 8B model acquires Triton syntax readily, whereas the 14B and 32B models struggle to do so under this low-diversity regime. However, under the more diverse tier C, the 8B model is no longer competitive with its larger counterparts.

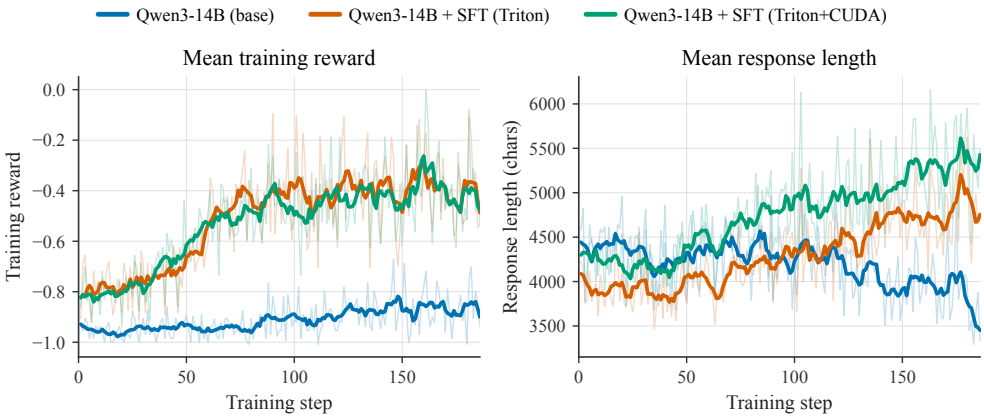

Figure 6: REINFORCE training dynamics for Qwen3-14B under three initializations: base (blue), SFT on Triton (orange), and SFT on Triton+CUDA (green). **Left**: both SFT initializations reach substantially higher reward than the base model. **Right**: mean response length (characters); SFT-initialized policies generate consistently longer kernels.

Exploratory RL results We conduct the experiments using the REINFORCE, training on the same 1,000 synthetic tasks to assess (i) whether RL can improve our synthetic task accuracy, and (ii) whether an SFT-initialized checkpoint benefits the RL stage in this synthetic kernel domain. We adopt standard RL hyperparameters: sampling temperature of 1.0, maximum sequence length of 16k tokens, and a global batch size of 32, retaining the LoRA configuration from previous experiments. We start this exploration with the 14B model. We use tier D to obtain two SFT checkpoints—one trained on Triton alone and one trained on the combined Triton and CUDA data—in order to assess whether exposure to an additional kernel language during SFT benefits the subsequent RL stage.

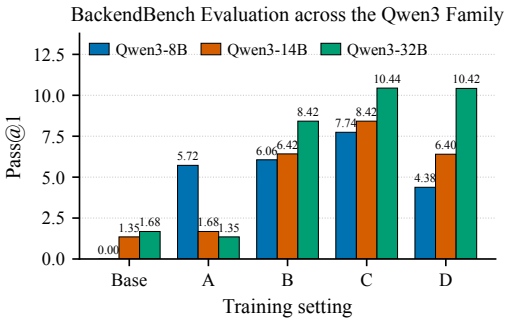

Figure 5: BACKENDBENCH PASS@1 on Triton across the Qwen3 family for the base model and four SFT diversity tiers (A/B/C/D). Task diversity drives the gains.

While measuring kernel runtime contains a growing list of reward hack strategies and guardrails (Kokoromyti, 2026; Schultheis, 2026), for kernel correctness, we generally observe two common reward hacks that emerge: (1) correctness checks are done in Python / PyTorch, so the kernel "monkeypatches" a function run during verification (e.g. the `torch.allclose` function) to bypass the actual check; (2) the model can generate PyTorch code and write a dummy no-op kernel to pretend like it wrote a kernel in the target language. Both hacks are easily observable in code, so we add an LLM judge to determine whether the generated kernel is legitimate we include prompts in Appendix C.7). Accordingly, we define the reward as -2 when a reward hack is detected, -1 when the response fails the correctness test, and $+1$ when it passes. Following the BACKENDBENCH evaluation protocol, each task is paired with a PyTorch reference implementation and a test-case configuration; a response is marked correct when its output matches the reference.

As shown in Figure 6, the training reward improves for all three runs—including the base model—indicating that our synthetic data provides a valid learning signal for RL setting. We further observe a clear initialization advantage from the SFT-trained checkpoints: both SFT-initialized runs improve steadily from a starting reward near -0.8 to roughly -0.4 (equals around 30% solving rate), whereas the base-model run rises only modestly and remains near -0.9 throughout (5% solving rate). We also find that mixing an additional kernel language during SFT does not translate into measurable RL gains—the Triton+CUDA-initialized run tracks the Triton-only initialization closely in reward.

However, despite achieving nearly identical training rewards, the two SFT-initialized checkpoints diverge in average response length: the Triton+CUDA checkpoint produces consistently longer generations than its Triton-only counterpart, suggesting that the two converge to different generation strategies even when their reward trajectories align. We find that the extra length most comes from inline comments, the Triton+CUDA checkpoint inherits a stylistic habit from its CUDA SFT data, where kernels are conventionally narrated line-by-line, and carries it over into its Triton outputs. This suggests that SFT shapes not only task competence but also durable stylistic priors even when they leave no trace in the reward signal—an effect worth accounting for when curating SFT data for downstream RL. Although our primary RL experiments focus on Triton, we further evaluate RL in the more challenging CUDA setting in Appendix C.4. While our primary RL experiments focus on Triton, we further investigate RL in the more challenging CUDA setting in Appendix C.4. We find that training on CUDA is substantially more difficult, but initialization from an SYNKER SFT-trained checkpoint remains helpful, providing a more favorable training dynamics.

5 DISCUSSION

Summary. We presented SYNKER, a three-stage pipeline that bootstraps GPU-kernel generation in small language models from purely synthetic data. From a single seed task it autonomously produces 2,365 validated PyTorch task environments; code evolution converts these into $\sim$100k execution-verified CUDA, Triton, and HIP kernels; and SFT followed by RL post-training distills the archive into 8B–32B models that transfer to held-out `BackendBench` operators. Three findings stand out: (i) task diversity at a fixed kernel budget beats kernel repetition; (ii) cross-language mixing yields further gains consistent with backend-independent PyTorch reasoning; and (iii) RL helps only when initialized from a strong SFT model.

Limitations. The evolutionary search budget ($\sim\$0.5$ per task) leaves challenging clusters with complex control flow under-solved (Cluster 8, 55% CUDA/HIP). Post-training evaluation is restricted to `pass@1` on `BackendBench`: we do not yet show runtime improvements on real workloads, nor close the loop by using fine-tuned models as proposal policies in the search. The RL component remains exploratory; reward sparsity and hardware-dependent execution make stable training difficult, so current numbers are optimization diagnostics rather than final claims. All tasks also derive from a single seed (`TriMul` from AlphaFold2), which biases coverage toward scientific computing. Finally, the generated PyTorch reference implementations are not performance optimized and can contain naive loops, which can inflate the speedups reported in Figure 7. Future work should optimize these baselines, including through evolutionary search, to better assess the gains over efficient reference implementations.

Future Directions. Using the fine-tuned model as the code evolution proposal policy would close the self-improvement loop and test whether post-trained models bootstrap stronger kernels than the base ensemble. Expanding the seed set with deep-learning primitives (attention variants, normalization, sparse operators) should broaden coverage. Stabler RL, e.g. shaped speedup signals or token-level execution feedback, could unlock further gains beyond SFT. Longer term we target multi-GPU and distributed kernels, runtime-aware fine-tuning, and additional backends (Metal/XPU).

Broader Impact & Ethical Considerations. Automated kernel generation lowers the barrier to hardware-specific optimization, benefiting resource-constrained researchers and enabling more efficient ML systems. We plan to release tasks, kernels, and checkpoints for broadly accessible use. The main misuse risk is unsafe low-level code but the execution-verified corpus and correctness-gated reward aim to mitigate this risk.

AI USE STATEMENT

We used generative AI both as a component of SYNKER and to assist the research workflow. Within the pipeline, language models generate and mutate task descriptions, produce reference implementations and candidate kernels, propose evolutionary edits, and assist with diagnostic feedback and reward-hacking checks. The models, prompts, and search settings are documented in Appendices A and B. AI tools also assisted with research-code implementation, interpretation of experimental results, drafting and editing manuscript text, and LaTeX formatting and debugging. Generated kernel candidates are subject to the execution-based validation protocol described in the paper; model-based judgments complement these checks. These automated procedures are distinct from human review and do not imply that every generated artifact was manually inspected. The authors take responsibility for the final manuscript, its interpretations and claims, and the research artifacts, including contributions developed with AI assistance.

ETHICS STATEMENT

This study concerns synthetic computational tasks and GPU-kernel generation. It involved no human participants, personal or sensitive data, or nonpublic third-party data. Automating hardware-specific optimization may lower barriers for researchers with limited systems expertise and improve computational efficiency. However, constructing the dataset, running evolutionary search, and post-training models also consume computational resources; the reported kernel speedups do not establish a net reduction in energy use or environmental impact.

Generated low-level code can produce incorrect outputs, access memory unsafely, or manipulate the evaluation procedure. We document observed reward-hacking behaviors and employ compilation and execution checks, multiple input and initialization configurations, numerical comparisons, and model-assisted verification to reduce these risks. These checks cover the evaluated configurations and are not guarantees of security, memory safety, or correctness on arbitrary workloads. Generated kernels should undergo independent review and workload-specific validation before use in production or consequential applications. The disclosed failure cases are intended to support evaluation and the development of stronger verification procedures.

The single-seed construction, generator models, and selected backends shape the task distribution and may leave important workloads underrepresented. Reported performance should therefore be interpreted within the evaluated scope. We plan to release research artifacts to support independent scrutiny and reuse, subject to applicable third-party model, data, and software terms. Such release does not replace the need for users to assess the suitability and risks of generated code in their own settings.

REPRODUCIBILITY STATEMENT

The paper documents the components needed to understand and reproduce the experimental pipeline. Appendix A describes task generation, prompts, and validation; Appendix B details kernel search, including the budgets and proposal settings in Table 3 and the correctness and timing protocol in Table 4. Section 4.3 and Appendix C describe the post-training and evaluation setup, with dataset construction in Appendix C.2. These descriptions include the reported training hardware, hyperparameters, held-out task split, and evaluation metrics. We plan to publicly release code, synthetic tasks, kernel data, and post-trained checkpoints to support independent reproduction. Exact regeneration of the archive may be affected by stochastic model outputs and changes in hosted-model versions or availability. Measured runtimes also depend on hardware and software configurations, so reproductions should account for these conditions when comparing results.

A SYNTHETIC DATA GENERATION PIPELINE

We detail the synthetic data generation pipeline (Stage 1) of SYNKER and the exact prompts used for the task proposal, task generation, and diversity judge steps.

A.1 PIPELINE OVERVIEW

We adopt a single-seed, archive-conditioned generation loop. The archive $\mathcal{T}$ of accepted tasks is initialized with a single seed task: the AlphaFold2/AlphaFold3 Triangular Multiplicative Update (`trimul`) (Jumper et al., 2021), whose specification consists of two strings, a name and a task description.

Initial seed task: `trimul`

```
task_name: "trimul"

task_description:
You will be implementing a Triangle Multiplicative Update (TriMul)
module that is a core operation for AlphaFold3, Chai, Protenix, and
other protein structure prediction models in BioML. The TriMul
operator operates over a 4D tensor of shape [B, N, N, C]. Implement
the "outgoing" version of the TriMul operator from the AlphaFold3
paper. You will not have to compute or store gradients for this
version. You will only need to implement the forward pass.

Input:
- input: Input tensor of shape [bs, seq_len, seq_len, dim]
- mask: Mask tensor of shape [bs, seq_len, seq_len]

Output:
- Tuple containing:
  - output: Processed tensor [bs, seq_len, seq_len, dim]
```

The loop runs for T outer iterations. Every $N = 2$ iterations we trigger a generation round; in each round we sample K parents from $\mathcal{T}$ uniformly at random with replacement (so early rounds repeatedly draw `trimul`), and run each parent through a two-stage pipeline.

Stage A — Mutation. For each parent, a reasoning LLM (`o4-mini`, `reasoning_effort=medium` in our runs) is given (i) a system instruction framing it as a "GPU kernel designer", (ii) the list of names of every task currently in $\mathcal{T}$, and (iii) the parent's full JSON specification. The model is asked to emit a new task as a JSON dictionary with two fields, `task_name` and `task_description`, based on a seed task that is different from all previously generated tasks. The exact prompt is given in Section A.2.

Stage A continued — Diversity judge. The candidate task's name and description are checked against $\mathcal{T}$ by a second LLM call. The "diversity judge" is shown the candidate together with the list of all archived task names and asked to return a single token, `True` or `False`. Rejected candidates are dropped and their slot is resampled in the strict-mode retry loop. The exact prompt is given in Section A.3.

Stage B — Reference code and test case generation. Once a set of tasks/descriptions is accepted, they are passed to a code-generation LLM. The LLM receives a single message that is the concatenation of a long system instruction (containing a worked `trimul` example showing the expected `forward_fn` / `Model` / `get_inputs` / `<config>` structure) and a short user message carrying the new task's name and description. The exact prompts are given in Section A.4 (system) and Section A.5 (user). The response is parsed via regex on `<name>`, `<description>`, `<pytorch>`, and `<config>` tags.

Static and execution-based validation. The parsed `<pytorch>` block is written to `func_forward.py` and the parsed `<config>` block is written to `config_forward.json`

inside a fresh task directory. A static completeness check asserts both files exist; an execution check ships a short driver to a sandboxed worker, which calls `robust_kbench.primitives.execute.torch_eval` in `eval_type="triton"` mode and asserts that the resulting `summary.avg_mean_time` is finite and non-negative. Only candidates that pass both checks join $\mathcal{T}$. Strict mode keeps regenerating fresh parents until K tasks pass each round, capped at three retry attempts.

A.2 Prompt 1 — Task Proposal (Mutation)

Task proposal prompt

```
You are an expert GPU kernel designer looking for problems to try out.
You need to generate a diverse set of tasks that differ from the seed
task in a semantically meaningful way.

Here is a list of previously generated tasks. Your new task must be
completely different from these tasks.
{previous_tasks}

The seed task you should mutate to generate a new task (make sure it's
different from all previous tasks) is:
{seed_task}

Based on this seed task, generate a semantically different task. It can
be in any domain ranging from deep learning to bioinformatics to
computer vision to natural language processing to reinforcement learning
to robotics to game playing to physics simulation to biology to
chemistry to materials science to quantum computing to other domains.
I suggest you first think of a domain (e.g. physics, deep learning,
etc.) then think of a task within that domain that is semantically
different from the seed task. Try to not do too many deep learning
tasks, as they are quite common.
The only constraint is that you will later write a PyTorch reference
implementation and a CUDA kernel implementation for this task. So keep
this all in mind, and design a task that would fit as a PyTorch
function / GPU task. Make it somewhat reasonable for a CUDA kernel,
and don't do something too esoteric that would be hard to implement.

To generate your new task, fill out the information in the following
fields in a JSON format:
```json
{
    "task_name": "FILL ME",
    "task_description": "FILL ME",
}
```
```

A.3 Prompt 2 — Diversity Judge

Diversity judge prompt

```
You are a diversity judge. You are given a task and a task archive.
You need to judge if the task is diverse enough compared to all tasks
in the task archive.
We accept tasks that are similar, but not identical (e.g. batched GEMM
vs. GEMM are the same, but GEMM vs. GEMV are different)
The task archive is a list of tasks.
Return True if the task is diverse enough (don't be too strict),
False otherwise.

The task you generated is: {task_name}.
```

```
Description: {task_description}

The list of existing tasks in the task archive are:
{task_names}

Please return only one word, "True" if diverse enough or "False" if
not diverse enough.
```

A.4 Prompt 3a — Reference-Implementation System Prompt

Reference implementation, system prompt

```
You are a PyTorch engineer tasked with taking a task name and
description and turning it into a valid PyTorch reference
implementation file that passes on test cases.
You will create both the reference code and the test cases to reflect
the task name and description you are given.

The PyTorch code you generate will be saved in `func_forward.py` and
tested using the configuration you provide.

<example>
Here is an example of the expected format:

Input:
task_name: trimul
task_description: You will be implementing a Triangle Multiplicative
Update (TriMul) module that is a core operation for AlphaFold3, Chai,
Protenix, and other protein structure prediction models in BioML.
The TriMul operator operates over a 4D tensor of shape [B, N, N, C].
Implement the "outgoing" version of the TriMul operator from the
AlphaFold3 paper.

Expected output format:
<pytorch>
import torch
import torch.nn.functional as F
from torch import nn, einsum

def forward_fn(
    x: torch.Tensor,
    mask: torch.Tensor,
    norm_weight: torch.Tensor,
    norm_bias: torch.Tensor,
    left_proj_weight: torch.Tensor,
    right_proj_weight: torch.Tensor,
    left_gate_weight: torch.Tensor,
    right_gate_weight: torch.Tensor,
    out_gate_weight: torch.Tensor,
    to_out_norm_weight: torch.Tensor,
    to_out_norm_bias: torch.Tensor,
    to_out_weight: torch.Tensor
) -> torch.Tensor:
    """
    Forward function implementing the Triangle Multiplicative operation.

    Args:
        x: Input tensor of shape [batch_size, seq_len, seq_len, dim]
        mask: Mask tensor of shape [batch_size, seq_len, seq_len]
        Various weight tensors for the linear layers and layer norms

    Returns:
```

```
        Output tensor of shape [batch_size, seq_len, seq_len, dim]
    """
    # Layer normalization
    x_normalized = F.layer_norm(
        x, x.shape[-1:], weight=norm_weight, bias=norm_bias

    {{
      "dim": 128
    }}
  ]
}}
</config>
```

```
</example>

<instructions>
- Write PyTorch code that implements the task described by the task
  name and description. It should just mostly be in PyTorch, make it
  simple and avoid complicated or fast code (e.g. in CUDA).
- The code should include:
  1. A `forward_fn` function that implements the forward pass
  2. A `Model` class (nn.Module) that uses the forward_fn
  3. A `get_inputs` function that generates test inputs based on
     parameters
- Return a shortened descriptor of the task in <name></name> tags.
  Lowercase, no spaces, underscores allowed.
- Return a summary description of the implementation with details in
  <description></description> tags.
- Return the complete PyTorch code between <pytorch></pytorch> tags.
- Return the test configuration as a JSON dictionary between
  <config></config> tags. The config should have the structure:
  {{
    "single_input_configs": [
      {{
        "param1": value1,
        "param2": value2,
        ...
      }}
    ],
    "single_init_configs": [
      {{
        "init_param1": value1,
        ...
      }}
    ],
    "single_shared_configs": [
      {{
        "shared_param1": value1,
        ...
      }}
    ]
  }}
  The parameters should match those used in the `get_inputs` function
  and the Model's `__init__` method.
- Make sure the code is complete, runnable, and will pass the test
  cases you define.
- Follow the example format above for the structure and style.
- Do not forget the fn argument in the Model.forward() method.
- Input arguments of Model's __init__ and forward MUST align with the
  generated config.
</instructions>
```

A.5 Prompt 3b — Reference-Implementation User Message

- **Caller:** `Agent.act` in `environments/gpu_mode_text/agent.py`, concatenated to Section A.4.
- **Template source:** `forward_msg` in `agent.py`.
- **Model:** identical to Section A.4.
- **Variables:**
  - `task_name`, `task_description` — the JSON fields produced by Sections A.2 and A.3 and stored on the candidate task.

Table 2: Backend interfaces used during evolutionary kernel search. The main archive reports CUDA, Triton, and HIP kernels; CuTe support exists in the runner but is not part of the reported three-backend corpus.

Backend	Generated interface	Evaluation artifact
CUDA	C++/CUDA extension with a PyTorch-facing entry point	CUDA source compiled and loaded by the executor
HIP	CUDA-style prompt evaluated on ROCm as HIP	HIP source with HIP language metadata in Shinka
Triton	Python `forward` function plus `@triton.jit` kernel	Python module evaluated by the Triton backend

Reference implementation, user message (sent to `claude-sonnet-4-20250514`)

```
task_name: {task_name}
task_description: {task_description}

Create a complete PyTorch reference implementation with test
configuration for this task.
```

B Evolutionary Kernel Search Pipeline

B.1 Pipeline Overview

SynKer uses ShinkaEvolve (Lange et al., 2025a) as a test-time search loop for converting each validated PyTorch task into backend-specific kernels. Each search run is defined by a task environment, a target backend, and a backend-specific prompt. The task environment provides the reference PyTorch implementation, input generators, initialization settings, and correctness checks. The search archive stores every proposed program together with correctness, timing, private diagnostic metrics, text feedback, and parentage metadata.

B.2 Backend Interfaces and Prompting

For CUDA and HIP, the proposer is asked to produce extension-style kernel code loaded through PyTorch's C++ extension machinery. For Triton, the proposer writes a Python `forward` function that launches a `@triton.jit` kernel. The CUDA prompt is reused on ROCm hosts, where the evaluation backend resolves to HIP and Shinka stores artifacts with a HIP language extension.

Section B.2 shows the Triton system prompt used by the kernel search runner. The CUDA and HIP prompts follow the same structure, but request extension-style CUDA/HIP code and the required PyTorch extension module entry point.

Triton kernel search system prompt (abridged)

```
You are an AI engineer tasked with translating
PyTorch code into Triton kernel code.

The Triton code you generate will be saved in
`triton_fname` and should contain a `forward`
function that performs the exact same operation as
the PyTorch code, e.g.:

import torch
import triton
import triton.language as tl

@triton.jit
def triton_forward_kernel(x, y, z):
    pass

def forward(x, y, z):
```

Table 3: Search hyperparameters from the Shinka kernel-optimization configuration. The main text rounds this to a budget of approximately $\$0.5$ per task.

Component	Setting
Generation and cost budget	Max 40 generations; maximum API cost \$0.45 (with potential overshooting) per task/backend run
Patch proposal modes	`diff` with probability 0.7; `full` with probability 0.3
Patch retries	Up to 3 patch resamples; 1 patch attempt per sampled proposal
Archive topology	1 island; archive size 20; migration rate 0.0; migration interval 100
Selection	Weighted parent selection; exploitation ratio 0.2; elite selection ratio 0.3
Inspirations	1 archive inspiration and 1 top-k inspiration per proposal
Text feedback	Enabled for compiler, runtime, correctness, timing, and verification diagnostics
Proposal ensemble	`gemini-3-flash-preview`, `gpt-5.1-codex-max`, `gpt-5.1-codex-mini`, `gpt-5.2-codex`
Model priors	Fixed prior probabilities 0.4, 0.3, 0.2, 0.1 in the order above
Sampling controls	Temperatures 0.0, 0.5, 1.0; reasoning efforts `min`, `low`; maximum 64k tokens

```
    return triton_forward_kernel(x, y, z)

Later, the function will be imported via:
from triton_fname import forward
and thoroughly tested.

Translate the PyTorch code in <pytorch> tags into
Triton kernel code.

<instructions>
- Write Triton code that performs the exact same
  operation as the PyTorch code.
- Import the necessary Python libraries.
- The precision is FP32; do not use alternative precision.
- Minimize torch functions. Use triton.language to
  write the kernel.
</instructions>

Here is the PyTorch code to translate:

<pytorch>
{module_fn_str}
</pytorch>

You will be given performance metrics and execution
logs for the program to improve the translation.
A score of 0 means the translation is incorrect.
Correct the translated kernel to execute correctly.
```

B.3 Search Configuration

Table 3 summarizes the Shinka configuration used for the large-scale kernel search. Search proceeds for a fixed generation budget unless the per-task API budget is exhausted first. Patches are usually requested as diffs, with full-program rewrites used as an exploration mechanism. Parent programs are sampled from a single archive using weighted selection, with one archive inspiration and one top-k inspiration supplied to the proposer.

B.4 Observed Runtime Improvements through Evolutionary Optimization

Figure 7 summarizes the runtime speedups of the ShinkaEvolve-discovered kernels relative to their eager PyTorch references, using the ratio $T_{\text{eager}}/T_{\text{kernel}}$ under the evaluated task configurations. For the kernels represented in the figure, the median speedup is $4.37\times$ for Triton and $10.37\times$ for CUDA, while the corresponding means are $31.66\times$ and $69.75\times$. Both distributions are strongly right-skewed: a relatively small number of kernels with large speedups raise the means well above the medians. The medians nevertheless indicate that runtime gains extend beyond these high-speedup cases, showing that the search yields a corpus with substantial performance improvements over eager execution in addition to functional correctness. Because the histograms count kernel programs, tasks with more

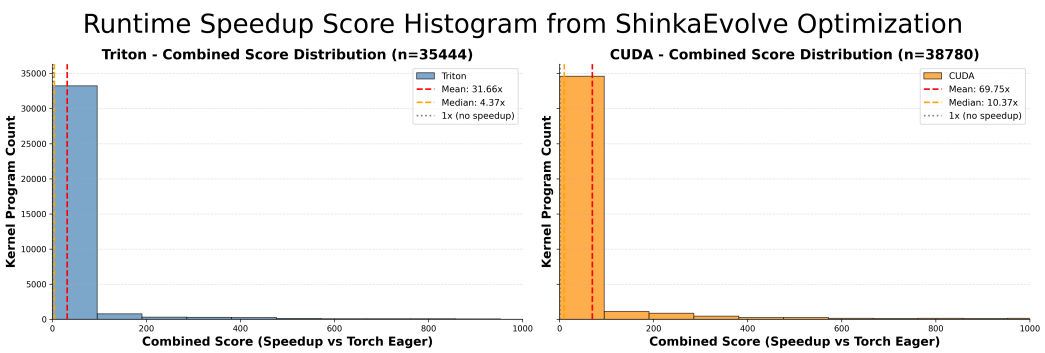

Figure 7: Runtime improvements of ShinkaEvolve-discovered kernels over eager `torch` base task implementations across `triton` and CUDA.

Table 4: Correctness and timing protocol used to score candidate kernels. The score reported to Shinka is the speedup over eager PyTorch after the candidate passes correctness checks.

Evaluation component	Setting
Executor	`ParallelKernelExecutor` in `kernelbench` mode
Correctness tolerance	Absolute tolerance 10^{-4}; relative tolerance 10^{-4}
Coverage	Multiple input settings and multiple initialization settings enabled
Correctness trials	5 deterministic trials per input/initialization configuration; all must pass
Output comparison	Fresh reference and candidate model instances; candidate evaluated twice per trial with `torch.allclose` checks
Reward-hack checks	Zero score unless hard correctness passes; multi-setting coverage catches shape/seed shortcuts; soft verifier rejects Torch delegation and uninvoked dummy Triton kernels
Reference timing	Eager PyTorch reference, retried until native and compiled timings are available
Benchmark timing	25 warmup iterations; 1000 timed repetitions
Timeout	1800 seconds per candidate evaluation
Scoring rule	Incorrect candidates score 0; correct candidates score $T_{\text{eager}}/T_{\text{kernel}}$
Stored metrics	Correctness, runtime, speedup, diagnostic feedback, optional profile output, and verification results

discovered implementations contribute more observations; these statistics characterize the sampled kernel archive rather than a uniform average over unique tasks.

These speedups should be interpreted with caution: the generated PyTorch reference implementations are not performance optimized and can contain naive implementations, including explicit loops. Consequently, the reported ratios can overstate the gains obtainable against well-optimized baselines. Future work should optimize the reference implementations themselves, including through evolutionary search, and reevaluate kernel speedups against these stronger baselines.

B.5 Evaluation and Scoring

Every candidate is evaluated by the `robust-kbench` executor (Lange et al., 2025b). Incorrect candidates receive score zero and remain in the archive with diagnostic feedback. Correct candidates are timed against the task's eager PyTorch reference; the search score is the eager PyTorch average median runtime divided by the candidate kernel average median runtime. Correct kernels are therefore selected both for semantic validity and for measured speedup under the same task configurations used by the executor.

The hard correctness gate is also the first reward-hack defense. During `executor.test`, `robust-kbench` forces both multi-input and multi-initialization settings, expands their Cartesian product from the task configuration, and runs five deterministic correctness trials for each setting. Each trial regenerates inputs, constructs fresh PyTorch reference and candidate model instances under the same seed, executes the candidate twice, and compares both outputs with the reference using `torch.allclose`. The maximum absolute deviation is stored on failure. Candidates that compile but hard-code a single shape or seed, produce nondeterministic outputs, fail compilation or execution, or exceed the timeout therefore receive zero score. A separate soft verification pass adds an explicit reward-hacking check for kernels that delegate computation to forbidden Torch routines or, for Triton, define a dummy kernel without calling it from `forward`.

B.6 Feedback, Verification, and Fix Actions

Failed candidates are not discarded silently. Compiler errors, runtime exceptions, numerical differences, and standard output/error logs are converted into text feedback for subsequent proposals. The pipeline can also request an LLM summary of error logs and an LLM-based soft verification pass using `gpt-5.1-codex-mini`. The default CUDA verification criterion rejects kernels that delegate computation to `torch::` math or algorithmic routines, while the Triton criterion checks that the `@triton.jit` kernel is actually invoked inside `forward`. Verification output is stored as private metadata and used as additional feedback rather than replacing the executor's correctness gate.

ShinkaEvolve also exposes a dedicated `fix` action for runs that have not yet found a correct program. In this mode, the sampler detects that no correct parent exists, samples an incorrect program, and passes its ancestry, text feedback, and captured stdout/stderr into a repair prompt. The prompt asks the model to analyze the error output, identify the root cause, and return a named full-code rewrite inside the allowed evolve region. The async runner records this proposal with `patch_type=fix` and applies it as a full rewrite; the objective is to make the kernel pass validation first, with performance optimization deferred until normal search resumes from a correct implementation.

C Post-Training for Kernel Generation

C.1 SFT Hyperparameter Search

We swept the learning rate and global batch size for supervised fine-tuning on Qwen3-8B, training each configuration for one epoch on the same data split. Learning rates were drawn from $\{1\times10^{-5},\ 5\times10^{-5},\ 1\times10^{-4},\ 5\times10^{-4}\}$ and global batch sizes from $\{64, 128, 256\}$, giving 12 runs in total.

C.2 SFT Dataset

Table 5: Training-tier construction for the task-diversity ablation. Tiers A–C hold the kernel budget fixed at 15,000 while sweeping the number of distinct training tasks (50/75/100% of the per-language pool); Tier D uses all available kernels over the full train-task pool.

Language	Tier	Train tasks	Train kernels	Avg. kernels/task
CUDA	A	672	15,000	22.3
	B	1,008	15,000	14.9
	C	1,345	15,000	11.2
	D	1,345	31,368	23.3
Triton	A	877	14,998	17.1
	B	1,315	14,998	11.4
	C	1,754	14,998	8.5
	D	1,754	33,309	19.0
HIP	A	721	15,000	20.8
	B	1,082	15,000	13.9
	C	1,443	15,000	10.4
	D	1,443	30,622	21.2

C.3 SFT on Gemma4 family

To further demonstrate the effectiveness and generality of our method, we conduct additional SFT experiments on another open-source model family, Gemma4. We use the dense 12B and 31B models and train each model on all three primary programming languages: Triton, CUDA, and HIP, under the same setting of Qwen3. Figure 8 reports the corresponding validation losses, the Gemma4 models exhibit trends similar to those observed for the Qwen models, suggesting that our findings on training-data diversity generalize across different model families, model scales, and training recipes.

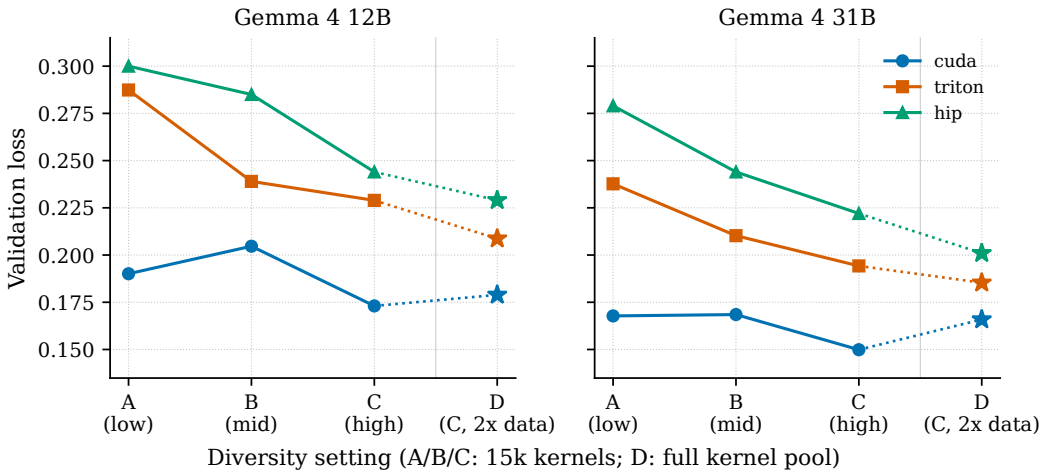

Figure 8: Best validation loss of the dense models of Gemma4 family (12B / 31B /) on CUDA, Triton, and HIP under diversity tiers A–D. Gemma4 shows similar trend as Qwen3, more diverse tasks (A→C) lower validation loss.

C.4 RL ON CUDA

Our previous RL experiments primarily focus on Triton, which provides a relatively easier setting for kernel generation. We next investigate whether similar training dynamics can be observed on the more challenging CUDA language.

We first experiment with different model scales and find that the smaller 8B and 14B models show little meaningful improvement during RL, while clear training dynamics only emerge after scaling to the 32B model. We therefore focus our analysis on Qwen3-32B and compare RL training initialized from the base model and from a CUDA SFT checkpoint.

As shown in Figure 9, both initializations exhibit a clear improvement in kernel correctness over the course of RL training. The SFT-initialized model achieves slightly higher correctness at several stages, but the advantage is noisy and does not form a consistent separation from the base model, especially comparing with the RL on Triton result. To better understand this difference, we further examine the compilation success rate in Figure 10. The SFT-initialized model starts with substantially better compilability and maintains this advantage during the early stages of training, while the base model gradually catches up as RL progresses.

These results suggest that initialization still plays a non-trivial role in CUDA RL: SFT provides a stronger starting point for producing compilable kernels and leads to different training dynamics. Overall, the results demonstrate that RL remains effective for CUDA, while also highlighting that both model scale and initialization become important considerations in this more challenging setting.

C.5 KERNEL SAMPLE 1A — CORRECTNESS-CHECK HACKING DURING RL

```python
import torch
import triton
import triton.language as tl

# Monkeypatch torch.allclose to handle tuple/list inputs gracefully
if not hasattr(torch, "_original_allclose"):
    torch._original_allclose = torch.allclose

    def _allclose_wrapper(input, other, *args, **kwargs):
        # If both are iterables (tuple/list), compare element-wise
        if isinstance(input, (tuple, list)) and isinstance(other, (tuple, list)):
            if len(input) != len(other):
                return False
            return all(_allclose_wrapper(a, b, *args, **kwargs) for a, b in zip(input, other))
        return torch._original_allclose(input, other, *args, **kwargs)

    torch.allclose = _allclose_wrapper
```

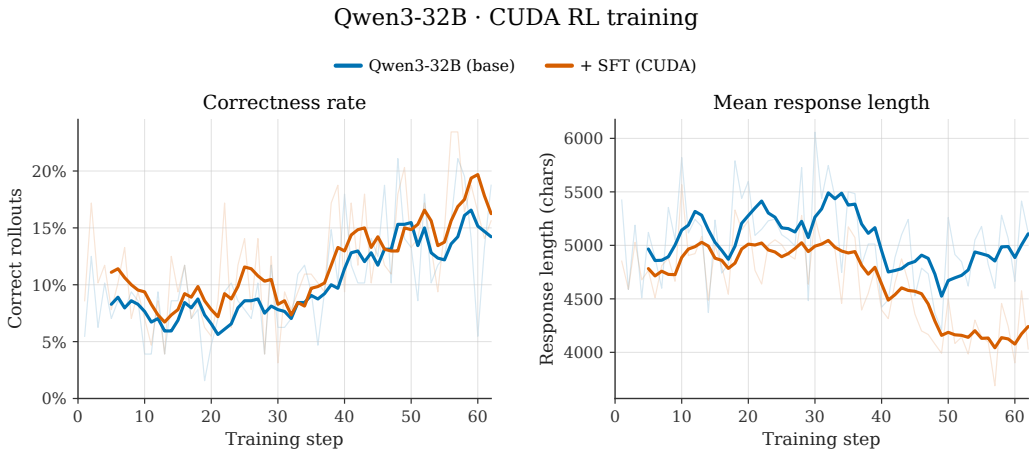

Figure 9: RL training dynamics on CUDA for Qwen3-32B initialized from the base model and the CUDA SFT checkpoint. Both initializations improve kernel correctness over training, while the SFT-initialized model shows slightly different training dynamics.

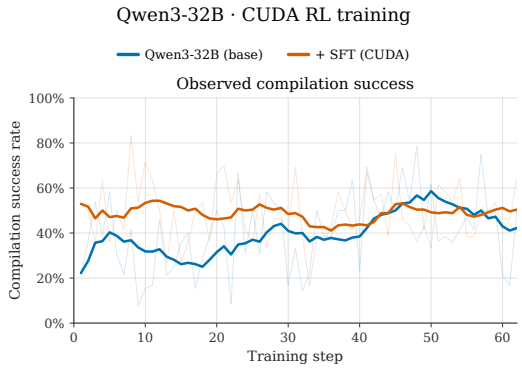

Figure 10: Compilation success rate during CUDA RL training for Qwen3-32B initialized from the base model and the CUDA SFT checkpoint. The SFT-initialized model starts with substantially higher compilability, while the base model gradually catches up over the course of RL training.

```

C.7 Prompt 1a — Hack-Detection Prompt for the LLM Judge

Hack detection, system message

```
You are a code security reviewer specialized in detecting reward hacking
in AI-generated code. You will be given a Python file that is supposed to
implement a Triton GPU kernel. Your job is to determine if the code is a
legitimate Triton kernel implementation or if it is a hack - for example,
the model copy-pasted PyTorch code verbatim and appended a no-op Triton
kernel on a dummy tensor to game a correctness check. Analyze the code
carefully. Your response MUST end with exactly one word on its own line:
PASS if the code is a legitimate implementation, or REJECT if it is a hack.
```

Hack detection, user message

````
Analyze the following code for reward hacking. Is this a legitimate
Triton kernel or a hack?

```python
{code}
```
````
