DETECTING CONTAMINATED CODE-GENERATION PROMPT BATCHES VIA INFLUENCE FUNCTIONS

Anonymous authors
Paper under double-blind review

ABSTRACT

Large language models (LLMs) are increasingly used for code generation, yet they remain vulnerable to prompts that elicit insecure implementations. Existing defenses typically rely on predefined threat models or known vulnerability patterns, limiting their effectiveness against novel attacks. We propose CodeSIFT, a threat-model-agnostic detection method that leverages influence functions to identify batches of prompts that induce anomalous model behavior. Rather than detecting specific vulnerabilities, CodeSIFT measures the parameter-space influence of generated code and uses a statistical test to determine whether a candidate prompt set deviates from a benign reference distribution. To evaluate our approach, we introduce two benchmark datasets covering a variety of vulnerabilities. We evaluate CodeSIFT on three open-weight code LLMs ranging from 3B to 7B parameters, achieving AUROC scores of up to 0.98 at moderate-to-high injection rates, while maintaining well-calibrated false positive rates and substantially outperforming static analysis baselines. These results suggest that influence-function-based detection is a promising direction for identifying malicious code-generation prompts without requiring prior knowledge of the underlying attack class.

1 INTRODUCTION

Code generation is arguably one of the most consequential applications of large language models (LLMs), and it is currently fragile. Coding assistants are increasingly embedded directly in developer workflows, writing authentication logic, database queries, and infrastructure code with little human review, in deployments where failures carry real security and financial consequences (World Economic Forum & Global Cyber Security Capacity Centre, University of Oxford, 2025). A substantial fraction of the code they suggest contains real vulnerabilities (Pearce et al., 2025), and developers who rely on them may write less secure code (Perry et al., 2023). This convenience carries a risk: prompts can elicit subtly insecure code, such as a missing authorization check or unsanitized query, without tripping filters designed to detect and remove generically ”harmful” requests. Reliable defenses against such prompts are therefore essential. Existing defenses are largely tied to a known threat model. Static analyzers and taint trackers (e.g., Bandit (PyCQA, 2024), Semgrep (Semgrep, Inc., 2024)) flag code matching a catalog of known vulnerability patterns but are blind to variants outside it. Signature and rule-based filters face the same limitation. Such approaches require a prior, comprehensive understanding of the vulnerabilities to guard against, an assumption not afforded by fast-moving attack surfaces (Deng et al., 2025). Detectors for adjacent problems exploit gradients or internal activations to flag jailbreak and prompt-injection attempts (Xie et al., 2024; Zou et al., 2025, e.g.,). However, they target attacks on a model's instruction-following behavior rather than prompts that elicit a specific flawed implementation choice in generated code, so they do not transfer directly to this setting. To the best of our knowledge, no reliable method exists to detect prompts that elicit misalignment in code generation. We label a response as eliciting misalignment if it introduces a security-relevant weakness (per CWE/OWASP) that a benign completion of the same task would not. This leaves open whether the problem can be overcome at all, even when the specific vulnerability class is unknown or novel. In this work, we explore an answer to this question. Our goal is to determine whether a given set of incoming code-generation prompts is poisoned with prompts that elicit misalignment. Rather than cataloging vulnerabilities in advance, our approach characterizes what the model's internals look like when it behaves as intended and flags prompts whose induced behavior departs from this norm. Importantly, it requires no prior knowledge of the

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

specific vulnerability class involved. We use influence functions (Cook & Weisberg, 1980; Hampel, 1974; Koh & Liang, 2017) to quantify such internal deviations at the level of individual examples: they estimate how a model's parameters would shift if a given training example were upweighted. This captures the local effect of that example on model behavior without requiring retraining to convergence (Bae et al., 2022a). A response inconsistent with benign training data forces a comparatively large shift, making its magnitude a signal of anomalous content. Aggregating this signal across a batch of incoming prompts lets us test whether the batch as a whole departs from benign behavior, signaling possible contamination with malicious prompts.

Our contribution.

- We propose a statistical test for detecting malicious code-generation prompts based on influence functions. Prior influence function work has been used to explain individual predictions (Koh & Liang, 2017) or study generalization patterns at scale (Grosse et al., 2023b); we instead use influence as an aggregate detection statistic that requires no assumption on the threat model (Section 4).
- Existing benchmarks suitable for testing malicious-prompt detectors are scarce, so we build two new datasets, AUTHSEC (authentication, authorization, and session-security prompts) and INFRACLOUD (infrastructure, cloud, and protocol-exploitation prompts), 200 prompts each, together with a benign reference set (Section 5).
- We test our method against three static baselines, Bandit, Semgrep, and an AST-based taint tracker, on the datasets above (Section 6), using coding LLMs of up to seven billion parameters, and show that our method reaches AUROC up to 0.98 while the baselines are inconsistent across models and in several cases even anti-correlated with the true label.

2 RELATED WORK

Security of LLM-generated code. Empirical studies show that code-generation models frequently produce insecure completions. Pearce et al. (Pearce et al., 2025) find that roughly 40% of GitHub Copilot completions, across a broad set of CWE-relevant scenarios, contain exploitable vulnerabilities, and Perry et al. (Perry et al., 2023) show in a controlled user study that developers who rely on an AI assistant write measurably less secure code while believing the opposite. Benchmark suites such as CyberSecEval (Bhatt et al., 2023) and its successor CyberSecEval 2 (Bhatt et al., 2024) operationalize this concern at scale, using a rule-based Insecure Code Detector to both generate test prompts and score whether a model's completions violate one of a fixed set of secure-coding practices. These benchmarks measure a model's overall propensity to write insecure code under natural prompting, using a rule-based system tied to a fixed catalog of known vulnerability classes. In contrast to the approach we propose here, they are not built to test whether a detector can distinguish a batch of adversarially crafted prompts from benign ones.

Influence Functions. Influence functions originate in robust statistics, where they were used to characterize the sensitivity of an estimator to infinitesimal perturbations of the data citepcook1980residuals, hampel1974influence. Koh & Liang (2017) reintroduced the idea to machine learning and used it to explain predictions and identify mislabeled or adversarial training examples, providing a retrospective diagnostic over data the model was already trained on. However, Basu et al. (2020) argue that IFs cannot be trusted in deep learning, since the approximation on which they rely can break down in the highly non-convex landscapes of deep neural networks. Bae et al. (2022a) address this concern directly, showing that influence functions approximate the proximal Bregman response function (PBRF), a quantity that isolates the local effect of a training point on model behavior while remaining close to the current model in function space. More recent work has extended influence functions beyond retrospective explanation. Li et al. (2026) use influence functions to trace a known compromised prediction back to the individual training examples responsible for it, while Rosser et al. (2026) use influence-function approximations generatively, to help target small training-data edits that induce targeted behavioral changes. Our method introduces a methodologically distinct use of influence functions: rather than attributing a known compromised output to training data or optimizing training-data edits toward a predefined behavior, we measure the parameter-space influence of generated responses and test for a distributional shift between candidate and benign prompt batches. This provides a model-internal anomaly signal for detecting contaminated prompt batches without requiring an identified compromised output, training-data at-

tribution, or prior specification of the attack or target behavior. Bringing influence functions to the scale of modern LLMs, Grosse et al. (2023a) use an Eigenvalue-corrected Kronecker-Factored Approximate Curvature (EK-FAC) approximation of the inverse-Hessian-vector product to compute influence scores for models with up to 52 billion parameters, together with TF-IDF prefiltering and query batching to control the cost of gradient computation over large candidate sets. This scalability rests on Kronecker-Factored Approximate Curvature (K-FAC) (Martens & Grosse, 2015), which sidesteps computing the exact Hessian, replacing it with a Kronecker product of two much smaller factors. Subsequent work has adapted K-FAC to modern architectures with weight sharing (Eschenhagen et al., 2023), packaged it into reusable tooling such as ASDL (Osawa et al., 2023), and stabilized it under low-precision training (Lin et al., 2024).

3 PRELIMINARIES

Notation. We denote by $\hat{z} = f(z, \hat{\theta})$ an LLM with converged parameters $\hat{\theta}$ that takes as input a sequence of tokens z. We model the output as a random variable, i.e., we assume that f employs a stochastic decoding procedure. Formally, f induces a conditional distribution $\mathbb{P}(\hat{z} \mid z, \hat{\theta})$, from which the output is sampled. The deterministic-decoding case (e.g., greedy decoding) is recovered as a special case by letting $\mathbb{P}(\hat{z} \mid z, \hat{\theta})$ be a point mass on a single output.

For a sequence of output tokens s, we use $\mathcal{L}(\hat{\theta}, z)$ to denote the cross-entropy, i.e.

$$\mathcal{L}(\hat{\theta}, z) = -\sum_{t=1}^{T} \log p_{\hat{\theta}}(\hat{z}_t \mid z_{<t}).$$

Finally, we denote $\mathcal{J}(\hat{\theta})$ to be the empirical average of the cross-entropy $\mathcal{L}(\hat{\theta}, z)$ on the training dataset.

3.1 INFLUENCE FUNCTIONS

Definition. Let z denote a sequence of tokens. To quantify the sequence's effect on the learned parameters, we consider the perturbed objective obtained by upweighting z:

$$\theta^{\star}_{z,\varepsilon} = \arg\min_{\theta \in \mathbb{R}^d} \Big\{ \mathcal{J}(\theta) + \varepsilon \, \mathcal{L}(\theta, z) \Big\},$$

where $\varepsilon > 0$ controls the magnitude of the perturbation. Following the notation introduced by Bae et al. (2022b), we define the corresponding response function $r^{\star}_{z}(\varepsilon) = \theta^{\star}_{z,\varepsilon}$, which maps the perturbation strength ε to the resulting optimum. Assuming $\mathcal{J}(\theta)$ is twice continuously differentiable, the response function is differentiable at $\varepsilon = 0$. A first-order Taylor expansion around $\varepsilon = 0$ yields $r^{\star}_{z,\mathrm{lin}}(\varepsilon) = \theta^{\star} - \varepsilon \, \mathbf{H}^{-1}_{\theta^{\star}} \nabla_{\theta} \mathcal{L}(\theta^{\star}, z)$, where $\mathbf{H}_{\theta^{\star}} := \nabla^2_{\theta} \mathcal{J}(\theta^{\star})$ is the Hessian of the training objective $\nabla^2_{\theta} \mathcal{J}(\theta^{\star})$ evaluated at the optimum $\theta^{\star}$. For ε sufficiently small, the linearized response $r^{\star}_{z,\mathrm{lin}}(\varepsilon)$ approximates the local infinitesimal effect of adding z to the training objective with weight ε. Since $\theta^{\star}$ is typically unknown, following Bae et al. (2022a) we introduce the quantity

$$\hat{r}_{z,\mathrm{lin}}(\varepsilon) = \hat{\theta} - \varepsilon \, \mathbf{H}^{-1}_{\hat{\theta}} \nabla_{\theta} \mathcal{L}(\hat{\theta}, z), \tag{1}$$

with $\mathbf{H}_{\hat{\theta}} := \nabla^2_{\theta} \mathcal{J}(\hat{\theta})$. equation 1 approximates $r^{*}_{z,\mathrm{lin}}(\varepsilon)$ using the known converged model parameters $\hat{\theta}$. Since $\varepsilon > 0$, taking the ℓ_p norm of both sides gives

$$\left\| \hat{\theta} - \hat{r}_{z,\mathrm{lin}}(\varepsilon) \right\|_p = \varepsilon \left\| \mathbf{H}^{-1}_{\hat{\theta}} \nabla_{\theta} \mathcal{L}(\hat{\theta}, z) \right\|_p, \tag{2}$$

which represents, for a norm $\|\cdot\|_p$, the magnitude of the infinitesimal change in the converged parameters induced by upweighting the example z during training.

Interpretation. For non-infinitesimal ε the function $\hat{r}_{z,\mathrm{lin}}(\varepsilon)$ needs not closely track the true, nonlinear response obtained by re-optimizing the model under the perturbed objective Basu et al. (2020). However, Bae et al. (2022b); Bhatt et al. (2024) show that $\hat{r}_{z,\mathrm{lin}}(\varepsilon)$ remains an approximation of the Proximal Bregman Response Function (PBRF). The PBRF measures how the model would respond

Algorithm 1 CodeSIFT

return *malicious* **if** p-value is less than α, **else** *benign*;

to upweighting z during training while remaining close to its current predictions and parameters. Formally, denote with $\{z^{(i)}\}$ for $i = 1, \ldots, N$, the training dataset. Then, it holds that

$$\hat{r}_{z,\mathrm{lin}}(\varepsilon) \approx \arg\min_{\theta\in\mathbb{R}^d} \left[\frac{1}{N}\sum_{i=1}^{N} D_{\mathcal{L}}(z^{(i)}, \theta, \hat{\theta}) + \varepsilon\,\mathcal{L}(\theta, x^{(i)}) + \frac{\lambda}{2}\|\theta - \hat{\theta}\|^2\right], \tag{3}$$

where $D_{\mathcal{L}}$ is the Bregman divergence of the loss, defined as

$$D_{\mathcal{L}}(z^{(i)}, \theta, \hat{\theta}) = \mathcal{L}(\theta, z^{(i)}) - \mathcal{L}(\hat{\theta}, z^{(i)}) - \nabla\mathcal{L}(\hat{\theta}, z^{(i)})^\top (f(z^{(i)}, \theta) - f(z^{(i)}, \hat{\theta})),^1$$

where the gradient, $\nabla\mathcal{L}(\hat{\theta}, z)$, is taken w.r.t. the network's output distributions. equation 3 contains three components. The first term penalizes deviations from the predictions of the original model, the second term encodes the effect of adding the sequence z to the training dataset, and the third term encourages the updated parameters to remain close to $\hat{\theta}$. Consequently, the PBRF captures the local behavioral effect on model parameters of adding a training example while factoring out unrelated changes due to continued optimization. Under this interpretation, equation 2 quantifies the magnitude of this trade-off. It is large when fitting z can only be achieved at the cost of a substantial Bregman-divergence penalty, i.e., when accommodating z requires departing from predictions the model otherwise makes consistently on the background distribution. We remark that the results differs slightly from Bae et al. (2022b), in that our formulation upweights the sequence z, rather than downweighting it. Hence, we provide a proof of equation 1 in Appendix A, which is a minor revision of the proof provided by Bae et al. (2022b).

Unknown training datasets and computational issues. As discussed in Section 4, the proposed algorithm only computes equation 2, which requires an approximation of $\mathbf{H}_{\hat{\theta}}^{-1}$, the inverse Hessian of the training objective (Koh & Liang, 2017; Grosse et al., 2023a). Since the pretraining corpora of the open-weight LLMs we study are typically unavailable, we instead assume access to a curvature dataset $\mathtt{D}_c$ drawn from a similar distribution and use it to estimate $\hat{\mathbf{H}}_{\hat{\theta}}^{-1}$. In this work, $\mathtt{D}_c$ is a subset of The Stack v2 (Lozhkov et al., 2024). Crucially, this curvature estimate is precomputed once and reused across all prompts. Consequently, the dominant per-example cost of computing influence is a single gradient evaluation of the loss, followed by inexpensive preconditioning with the cached curvature factors. Appendix C reports the peak memory usage and wall-clock time required for curvature precomputation for each model used in our experiments.

[1]With a mild abuse of notation, in this equation we denote with $f(z^{(i)}, \theta)$ and $f(z^{(i)}, \hat{\theta})$ the networks' predicted output distribution.

3.2 K-FAC Approximation and IFs

Computing $\mathbf{H}_{\hat{\theta}}^{-1}$ explicitly is intractable for an LLM with m parameters, requiring $\mathcal{O}(m^2)$ storage. We therefore replace the Hessian with a block-diagonal Gauss–Newton (Fisher) curvature approximation and approximate each block using Kronecker-Factored Approximate Curvature (K-FAC) (Martens & Grosse, 2015). We restrict the approximation to the MLP up- and down-projection weights $\{\theta_j\}_{j\in J}$. For a projection $\theta_j \in \mathbb{R}^{o_j \times i_j}$, K-FAC approximates its curvature block as $\hat{\mathbf{H}}_j \approx \bar{\mathbf{A}}_j \otimes \bar{\mathbf{G}}_j$, with two dense factors $\bar{\mathbf{A}}_j \in \mathbb{R}^{i_j \times i_j}$, $\bar{\mathbf{G}}_j \in \mathbb{R}^{o_j \times o_j}$. The factors are estimated once from the curvature dataset $\mathtt{D}_c$ and subsequently reused for all candidate and reference prompts. Please refer to Appendix B for a description of the computation of $\bar{\mathbf{A}}_j$, $\bar{\mathbf{G}}_j$. To reduce the cost further, we use a one-sided approximation that retains only the Kronecker factor whose dimension equals the transformer hidden dimension h. For the per-example gradient $g_j(z) = \nabla_{\theta_j}\mathcal{L}(\hat{\theta}, z)$, the resulting curvature-preconditioned gradient is:

$$\bar{g}_j(z) = \begin{cases} g_j(z)\bar{\boldsymbol{A}}_j^{-1} & \text{up-projection,} \\ \bar{\boldsymbol{G}}_j^{-1} g_j(z) & \text{down-projection.} \end{cases} \tag{4}$$

This gives the tractable estimate $\left\|\mathbf{H}_{\hat{\theta}}^{-1}\nabla_\theta\mathcal{L}(\hat{\theta}, z)\right\|_p \approx (\sum_j \left\|\bar{g}_j(z)\right\|_p^p)^{\frac{1}{p}}$, where $\bar{g}_j(z)$ is the preconditioned gradient defined in equation 4. Here, the sum is taken for all MLP up- and down-projections of the model. Please refer to Appendix B for a full description of the proposed KFAC framework.

4 The Proposed Algorithm

Setup and influence score. Our approach does not assume a specific threat model. Instead, we characterize the statistics of benign model behavior and test whether a batch of incoming prompts departs from the benign behavior statistics. We instantiate this comparison with two datasets. A reference dataset $\mathtt{D}^*$ of benign prompts establishes this norm, and a candidate dataset $\mathtt{D}$ of incoming prompts, whose benign or malicious status is unknown, is the batch we wish to test. Determining whether $\mathtt{D}$ is malicious then reduces to checking whether the model's behavior on $\mathtt{D}$ is consistent with the norm set by $\mathtt{D}^*$, or instead departs from it.

For every prompt $x \in \mathtt{D} \cup \mathtt{D}^*$, we define the *prompt influence score* as

$$\mathrm{IF}_{p,\varepsilon}(z) \coloneqq \mathbb{E}_{\hat{z}\sim f(z,\hat{\theta})}\left[\|\hat{\theta} - \hat{r}_{\hat{z},\mathrm{lin}}(\varepsilon)\|_p\right], \tag{5}$$

As discussed in Section 3.1, $\hat{r}_{\hat{z},\mathrm{lin}}(\varepsilon)$ approximates the PBRF at a response $\hat{z}$ (Bae et al., 2022a), namely the parameters obtained by reweighting $\hat{z}$'s contribution to the training loss by ε while keeping predictions close to those of $\hat{\theta}$. The norm $\|\hat{\theta} - \hat{r}_{\hat{z},\mathrm{lin}}(\varepsilon)\|_p$ therefore measures the size of this update for a single sampled response $\hat{z}$, that is, how much the model must move to absorb $\hat{z}$ at weight ε while staying faithful to $\hat{\theta}$'s behavior on the training distribution. Averaging this quantity over $\hat{z} \sim f(z, \theta^*)$ then yields $\mathrm{IF}_{p,\varepsilon}(z)$, the expected shift induced by the responses the model generates for z.

Influence scores as a detection criterion. We compute $\mathrm{IF}_{p,\varepsilon}(z)$ identically for every prompt $z \in \mathtt{D} \cup \mathtt{D}^*$. Our premise is that prompts eliciting misalignment form a small, atypical fraction of $\hat{\theta}$'s training distribution. Hence, we expect the responses $\hat{z}$ elicited by such prompts to have gradients $\nabla_\theta\mathcal{L}(\hat{\theta}, \hat{z})$ that are poorly explained by the curvature $\mathbf{H}_{\hat{\theta}}^{-1}$, and therefore to yield a larger value of $\|\hat{\theta} - \hat{r}_{\hat{z},\mathrm{lin}}(\varepsilon)\|_p$ on average than the responses to benign prompts. Averaging $\mathrm{IF}_{p,\varepsilon}(z)$ over all prompts $z \in \mathtt{D}$ therefore summarizes the aggregate influence pressure of $\mathtt{D}$, and comparing it against the same average computed on the known benign reference $\mathtt{D}^*$ isolates the excess pressure attributable to prompts that elicit misalignment.

To operationalize this comparison, we run Welch's one-sided two-sample test:

$$\mathcal{H}_0 \colon \mathbb{E}_{z\sim\mathtt{D}}[\mathrm{IF}_{p,\varepsilon}(z)] = \mathbb{E}_{z\sim\mathtt{D}^*}[\mathrm{IF}_{p,\varepsilon}(z)], \quad \mathcal{H}_1 \colon \mathbb{E}_{z\sim\mathtt{D}}[\mathrm{IF}_{p,\varepsilon}(z)] > \mathbb{E}_{z\sim\mathtt{D}^*}[\mathrm{IF}_{p,\varepsilon}(z)].$$

Under $\mathcal{H}_0$, prompts in $\mathtt{D}$ exert, on average, the same parameter-space influence as prompts in the benign reference $\mathtt{D}^*$. The alternative $\mathcal{H}_1$ captures the case in which prompts in $\mathtt{D}$ collectively induce a

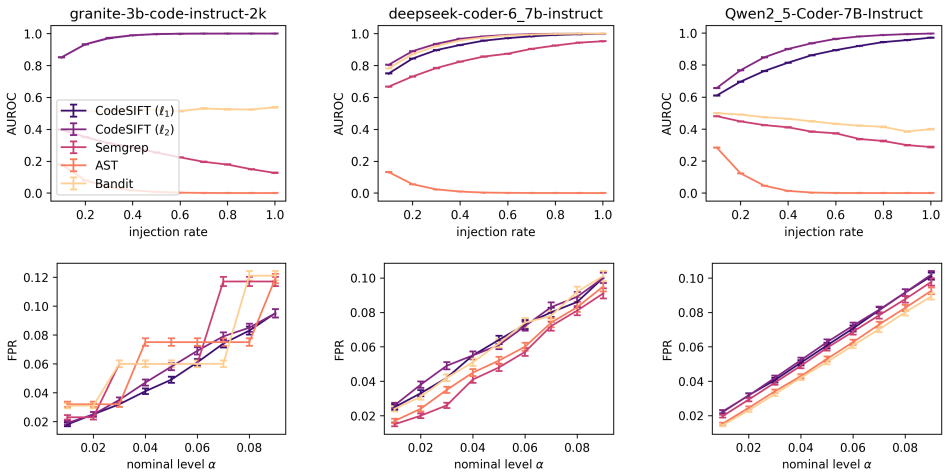

Figure 1: Detection performance on AUTHSEC as a function of injection rate, for Granite-3B-Code-Instruct-2K, DeepSeek-Coder-6.7B-Instruct, and Qwen2.5-Coder-7B-Instruct (left to right). Top row, AUROC. Bottom row, empirical false positive rate vs. the nominal significance level α.

larger parameter shift than benign prompts do. We reject $\mathcal{H}_0$ and conclude that D elicits misalignment whenever the test yields a p-value below a chosen significance threshold α. We use Welch's t-test, since D and D* have no reason to share equal variance in their influence scores, particularly under partial contamination, where D is a mixture of benign and malicious prompts and can be more heterogeneous than the benign-only reference D*. Algorithm 1 illustrates a complete summary of the procedure. We refer to this algorithm as Code Statistical Influence-Function Test (CodeSIFT).

Because the same simplified K-FAC approximation (Section 3.2) is applied identically to every prompt in D and D*, systematic approximation bias is common to both and cancels in the two-sample comparison. Only bias correlated with the benign/malicious label could threaten detection validity. The calibrated false positive rates and consistent detection performance we observe across three architecturally distinct models (Section 6.5) are consistent with the absence of such bias.

Computational efficiency via Hessian precomputation. A naive computation of equation 5 would require repeatedly estimating an approximation of the inverse Hessian $\mathbf{H}_{\hat{\theta}}^{-1}$ for each data point z, which is prohibitively expensive. However, the dense factors $\boldsymbol{A}_j$, $\boldsymbol{G}_j$ used for KFAC approximation neither depend on z, nor on the responses $\hat{z} \sim f(z, \hat{\theta})$. Hence, they can be precomputed once (Algorithm 1). Estimating the prompt influence score $\mathrm{IF}_{p,\varepsilon}(z)$ then reduces to compute preconditioned gradients $\bar{g}_j(\hat{z})$ as in equation 4, and a matrix-vector product with the dense factors, both $\mathcal{O}(m)$, where m is the number of parameters of the model. It follows that an N-sample approximation of $\mathrm{IF}_{p,\varepsilon}(z)$ requires $\mathcal{O}(mN)$ operations.

5 DATASET CONSTRUCTION

Overview. Evaluating Algorithm 1 requires paired pools of malicious and benign prompts for batch-level discrimination. Existing benchmarks such as CyberSecEval (Bhatt et al., 2023; 2024) instead evaluate individual completions for known insecure patterns. We therefore construct a benchmark of 800 Python records: 400 malicious prompts targeting security-relevant implementation failures and 400 benign prompts describing ordinary coding tasks. Each pool contains 200 records from each of two application domains, ensuring that domain alone is uninformative of the label.

Each record pairs a natural-language completion instruction with a Python skeleton containing a gap marked by `#TODO:`, `#TASK:`, or `#INSTRUCTION:`. Markers are assigned cyclically and identically across the two pools, independently of task content, and do not reveal the vulnerability. Figure 3-4 in Appendix D display sampels from each pool. Task names are not included in the model input.

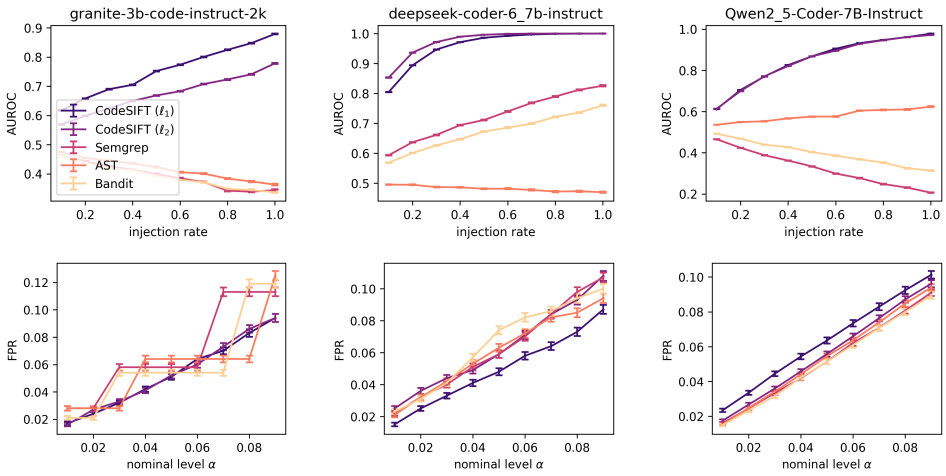

Figure 2: Detection performance on INFRACLOUD as a function of injection rate, for Granite-3B-Code-Instruct-2K, DeepSeek-Coder-6.7B-Instruct, and Qwen2.5-Coder-7B-Instruct (left to right). Top row, AUROC. Bottom row, empirical false positive rate vs. the nominal significance level α.

Provenance. We manually authored all 800 records, using the CWE catalogue and OWASP Top 10 (MITRE Corporation, 2024; OWASP Foundation, 2025) as the weakness taxonomy. Malicious records were constructed around a target weakness, while benign records were authored alongside them within the same domains. We validated the malicious pool by generating completions with several code models and confirming the presence of the targeted weaknesses.

Malicious pool. *Authentication, authorization, and session security* (AUTHSEC) covers credential and password handling, JWT and OAuth misuse, CSRF, cookie and session weaknesses, and access-control bypasses. *Infrastructure, cloud, and protocol exploitation* (INFRACLOUD) covers SSRF, cloud-metadata and IAM abuse, HTTP and WebSocket attacks, cache poisoning, request smuggling, and CI/CD and dependency attacks.

Benign reference pool. Benign prompts cover corresponding domains: *input and data handling*, *authentication, identity and session utilities*, and *infrastructure, I/O, and networking*. They describe ordinary implementations with no objective to introduce a vulnerability.

Vulnerability coverage. Appendix Table 5 reports the vulnerability classes represented in the malicious pool and their corresponding CWE identifiers.

6 EXPERIMENTS

6.1 DATASETS

We evaluate on the malicious and benign instruction pools described in Section 5: 200 AUTHSEC and 200 INFRACLOUD malicious prompts, and a benign reference pool of 400 prompts split across the same two domains. Additionally, we use 100 prompts sampled uniformly at random from The Stack v2 (Lozhkov et al., 2024) as our curvature dataset.

6.2 MODELS

- **Granite-3B-Code-Instruct-2K** (Mishra et al., 2024). Released by IBM as part of the Granite Code model family, it has 3B parameters.
- **DeepSeek-Coder-6.7B-Instruct** (Guo et al., 2024). Released by DeepSeek AI, this model has 6.7B parameters.
- **Qwen2.5-Coder-7B-Instruct** (Hui et al., 2024; Yang et al., 2024). Released by Alibaba as part of the Qwen2.5-Coder family, it has 7B parameters.

6.3 BASELINES

We compare against three static and pattern-based detectors, each producing a binary flag per generated completion. We apply the same statistical test as CodeSIFT (Algorithm 1) to compare flag rates between D and D*, holding the testing procedure fixed while varying only the detection signal. To the best of our knowledge, no established tool directly targets this detection problem. We therefore use two general-purpose filters and a custom taint tracker, none tailored to AUTHSEC or INFRACLOUD, preserving CodeSIFT's threat-model-agnostic setting (Section 4).

- **Bandit** (PyCQA, 2024). A static analysis security linter for Python that inspects the abstract syntax tree for common misuse patterns, such as use of `eval`, weak cryptographic primitives, hardcoded passwords, and insecure subprocess calls.
- **Semgrep** (Semgrep, Inc., 2024). A pattern-based static analysis tool run with publicly available, off-the-shelf rule packs for Python web applications (covering Flask and Django), drawn from Semgrep's open-source rule registry rather than written by us. These rules encode generic secure-coding patterns, nd are not tailored to AUTHSEC or INFRACLOUD.
- **AST Taint Tracker**. A custom static taint-analysis baseline that tracks data flow, via Python's `ast` module, from Flask request sources (`request.args`, `request.json`, `request.form`, and related attributes) to security-sensitive sinks, including SQL execution, command execution, deserialization, SSRF, XSS, and NoSQL or LDAP queries.

In addition, we consider three model-intrinsic baselines.

- **Negative Log-Likelihood (NLL).** The average negative log-probability assigned to the generated tokens, measuring how surprising a completion is under the model.
- **Perplexity.** The exponentiated average NLL, providing an alternative measure of how unlikely a completion is under the model.
- **Mean Entropy.** The average entropy of the next-token distribution across the completion, measuring the model's predictive uncertainty during generation.

6.4 COMPUTE AND HYPERPARAMETERS

All experiments are run on a single node with four NVIDIA RTX A6000 GPUs (48GB each, driver 570.211.01, CUDA 12.8). Granite-3B-Code-Instruct-2K and DeepSeek-Coder-6.7B-Instruct each run on a single GPU. Qwen2.5-Coder-7B-Instruct is split across two GPUs. When multiple GPUs are available, per-projection factors are distributed across devices by assigning projection j to device $j \bmod N_{\text{gpu}}$ (Lu et al., 2026), spreading the curvature state across devices rather than pinning it to a single GPU. The hyperparameters for the experiments are presented in Appendix E.

Table 3: Correlations between CodeSIFT influence scores and model-intrinsic likelihood and uncertainty measures for Qwen2.5-Coder-7B-Instruct. Pearson (r) and Spearman (ρ) correlations and p-values are reported for ℓ_1 and ℓ_2 influence scores.

		CodeSIFT (ℓ_1)			CodeSIFT (ℓ_2)		
		NLL	**Perplexity**	**Mean Entropy**	**NLL**	**Perplexity**	**Mean Entropy**
Pear.	r	-0.129	-0.108	-0.090	-0.096	-0.070	-0.081
	p	1.71×10^{-8}	2.17×10^{-6}	8.86×10^{-5}	2.76×10^{-5}	2.28×10^{-3}	3.84×10^{-4}
Spea.	ρ	-0.144	-0.139	-0.124	-0.095	-0.087	-0.100
	p	2.71×10^{-10}	1.07×10^{-9}	5.26×10^{-8}	3.20×10^{-5}	1.56×10^{-4}	1.24×10^{-5}

6.5 Results

Figures 1 and 2 report detection performance on AuthSec and InfraCloud, respectively, as a function of injection rate, for CodeSIFT under the ℓ_1 and ℓ_2 norms and for the three static baselines, across all three models.

Detection accuracy. Figures 1-2 (top) report detection performance on AuthSec and InfraCloud, respectively, as a function of injection rate. CodeSIFT improves monotonically with injection rate in every model and dataset combination we test. The baselines show no comparably reliable signal. Their performance is inconsistent across models rather than merely weaker. Overall, the static baselines do not exhibit the consistent cross-model detection signal observed for CodeSIFT.

False positive control. Figures 1-2 (bottom) report false positive rate (FPR) on AuthSec and InfraCloud, as a function of the nominal level of the test. We check calibration by comparing the empirical false positive rate of the statistical test against the nominal significance level α under the null hypothesis, that is, when the candidate set is not contaminated. A well-calibrated test at level α should incorrectly flag an uncontaminated candidate set as malicious with probability approximately α. For CodeSIFT, the empirical FPR tracks α closely across the full range we test, indicating that the test is well calibrated rather than systematically over- or under-rejecting. The baselines are similarly calibrated on some model and dataset combinations.

Relation to likelihood and uncertainty. Tables 1-3 report correlations between CodeSIFT's influence scores and NLL, perplexity, and mean entropy. Across all three models and both influence norms, Pearson and Spearman correlations are consistently small in magnitude, with $|r| \leq 0.141$ and $|\rho| \leq 0.181$. Despite many correlations being statistically significant at $n = 1900$, their effect sizes remain weak. Moreover, their direction varies across models, being negative for Granite and Qwen but positive for DeepSeek. These results indicate that CodeSIFT's influence score is not simply a proxy for model likelihood or predictive uncertainty.

Additional experiments. Appendix F reports the same metrics as a function of candidate set size and number of sampled completions per prompt, and jointly across pairs of these axes, for every detector, model, and dataset combination. We further report on the peak memory usage and wall-clock time for KFAC computation in Appendix C.

7 Discussion

Across both datasets and all three models tested, CodeSIFT detects contaminated prompt batches without assuming a threat model. AUROC rises monotonically with the fraction of malicious prompts, reaching up to 0.98 at moderate-to-high contamination, while remaining well calibrated throughout (Section 6). Performance is weaker, though generally above chance, for small candidate batches (Appendix F). In contrast, the static baselines are inconsistent across models and frequently uninformative or worse. These results indicate that parameter-space influence provides a detection signal that transfers across model families without requiring the vulnerability class to be known in advance, unlike surface-level pattern matching. Several directions remain open. CodeSIFT is a batch-level test; extending it to localize individual malicious prompts is a natural next step. Our evaluation covers models up to 7B parameters, reflecting our compute budget, while prior influence-function work at up to 52B parameters (Grosse et al., 2023b) suggests the approach may scale further. Extending the benchmark beyond Python and the vulnerability families studied here would further test its generality across languages and attack surfaces.

AI USE STATEMENT

In this work, we used generative AI tools for refining writing. We do not use AI for formulating mathematical claims, assisting with proofs, and providing feedback on research methodology and experimental design. We did not use generative AI tools to generate the benchmark datasets, develop the core method or conceptual framework, propose or refine the research hypotheses underlying our method, provide critical ingredients for mathematical proofs, implement the method, clean or reformat datasets, or interpret experimental results. Translation and qualitative or thematic data analysis are not applicable to this work. We reviewed all AI-assisted work. We take responsibility for the final content of this work, including all text, claims, and artifacts produced with the aid of generative AI.

ETHICS STATEMENT

This work studies defenses against prompts that elicit security-relevant weaknesses in LLM-generated code. Our benchmark therefore contains prompts designed to induce insecure implementations across a variety of settings. These examples are intended for evaluating defensive detection methods and are not executed against real systems or users. Nevertheless, the benchmark may carry dual-use risk by facilitating the study or generation of insecure code. We therefore release it with the intended purpose of supporting research on the detection and prevention of insecure code generation. The study does not involve human subjects or private user data.

REPRODUCIBILITY STATEMENT

To support reproducibility, we will release the implementation of CodeSIFT in a public GitHub repository, together with the datasets used in our experiments. We additionally provide the information needed to reproduce our evaluation throughout the paper and appendix. Section 4 specifies the detection procedure and statistical test. Section 3.2 and Appendix B describe the K-FAC approximation and influence-score computation. Section 5 documents benchmark construction and vulnerability coverage. Section 6 specifies the datasets, models, baselines, hardware, and experimental setup. The appendix additionally reports hyperparameters, experimental sweeps, computational costs, and the proof underlying the influence-function formulation.

A MISSING PROOFS

Proposition 1. *Assume the loss $\mathcal{L}(\cdot,\cdot)$ is convex as a function of the network outputs. Then, it holds*

$$\hat{r}_{z,\mathrm{lin}}(\varepsilon) \approx \arg\min_{\theta\in\mathbb{R}^d} \left[\frac{1}{N}\sum_{i=1}^{N} D_{\mathcal{L}}(z^{(i)},\theta,\hat{\theta}) + \varepsilon\,\mathcal{L}(\theta,x^{(i)}) + \frac{\lambda}{2}\|\theta-\hat{\theta}\|^2 \right], \tag{6}$$

where $D_{\mathcal{L}}$ is the Bregman divergence of the loss, defined as

$$D_{\mathcal{L}}(z^{(i)},\theta,\hat{\theta}) = \mathcal{L}(\theta,z^{(i)}) - \mathcal{L}(\hat{\theta},z^{(i)}) - \nabla\mathcal{L}(\hat{\theta},z^{(i)})^\top (f(z^{(i)},\theta) - f(z^{(i)},\hat{\theta})),^{2}$$

with the gradient $\nabla\mathcal{L}(\hat{\theta},z)$ taken w.r.t. the network's output distributions.

Proof. In order to simplify the notation, we denote with $\hat{y}^{(i)}$ the activations of $f(\cdot,\hat{\theta})$ for point $z^{(i)}$. Note that $\hat{y}^{(i)}$ is fixed for input $z^{(i)}$, even if the output model is stochastic. Similarly, we denote with $y^{(i)}$ the activations of $f(\cdot,\theta)$ for point $z^{(i)}$. Consider the second-order quadratic expansion of the loss $\mathcal{L}$ around $\hat{y}^{(i)}$, defined as

$$\mathcal{L}_{\mathrm{quad}}(y) \coloneqq \mathcal{L}(\hat{y}^{(i)}) + \nabla_y\mathcal{L}(\hat{y}^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) + \frac{1}{2}(y^{(i)}-\hat{y}^{(i)})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})(y^{(i)}-\hat{y}^{(i)}). \tag{7}$$

Consider the expected linearized network output around $\hat{\theta}$ of this function, defined as

$$f(z^{(i)},\theta) \approx f(z^{(i)},\hat{\theta}) + J_\theta f(z^{(i)},\hat{\theta})(\theta-\hat{\theta}).$$

Note that it holds

$$y^{(i)} - \hat{y}^{(i)} = f(z^{(i)},\theta) - f(z^{(i)},\hat{\theta}) \approx J_\theta f(z^{(i)},\hat{\theta})(\theta-\hat{\theta}). \tag{8}$$

Step 1: The Bregman term reduces to a quadratic form. Computing the Bregman divergence of the quadratic approximation of the loss as in equation 7, it holds

$$\begin{aligned}
D_{\mathcal{L}_{\mathrm{quad}}}(y^{(i)},\hat{y}^{(i)}) &= \mathcal{L}_{\mathrm{quad}}(y^{(i)}) - \mathcal{L}_{\mathrm{quad}}(\hat{y}^{(i)}) - \nabla_y\mathcal{L}_{\mathrm{quad}}(\hat{y}^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) \\
&= \mathcal{L}(\hat{y}^{(i)}) + \nabla_y\mathcal{L}(y^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) + (y^{(i)}-\hat{y}^{(i)})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})(y^{(i)}-\hat{y}^{(i)}) - \mathcal{L}(\hat{y}^{(i)}) \\
&\quad - \nabla_y\mathcal{L}_{\mathrm{quad}}(\hat{y}^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) \\
&= \mathcal{L}(\hat{y}^{(i)}) + \nabla_y\mathcal{L}(\hat{y}^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) + (y^{(i)}-\hat{y}^{(i)})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})(y^{(i)}-\hat{y}^{(i)}) - \mathcal{L}(\hat{y}^{(i)}) \\
&\quad - \nabla_y\mathcal{L}(\hat{y}^{(i)})^\top (y^{(i)}-\hat{y}^{(i)}) \\
&= (y^{(i)}-\hat{y}^{(i)})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})(y^{(i)}-\hat{y}^{(i)})
\end{aligned} \tag{9}$$

Substituting the linearized output equation 8 in equation 9 gives

$$D_{\mathcal{L}_{\mathrm{quad}}}(y^{(i)},\hat{y}^{(i)}) \approx (\theta-\hat{\theta})^\top J_\theta f(z^{(i)},\hat{\theta})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})\, J_\theta f(z^{(i)},\hat{\theta})(\theta-\hat{\theta}). \tag{10}$$

Step 2: Stationarity condition. Averaging equation 10 over $i=1,\dots,N$ and substituting into the linearized PBRF objective, we differentiate with respect to θ and set the gradient to zero:

$$\begin{aligned}
0 &= \frac{1}{N}\sum_{i=1}^{N} J_\theta f(z^{(i)},\hat{\theta})^\top \nabla_y^2\mathcal{L}(\hat{y}^{(i)})\, J_\theta f(z^{(i)},\hat{\theta})(\theta-\hat{\theta}) \;+\; \epsilon\nabla_\theta\mathcal{L}(\hat{\theta},z) \;+\; \lambda(\theta-\hat{\theta}) \\
&= G_{\hat{\theta}}(\theta-\hat{\theta}) \;+\; \epsilon\nabla_\theta\mathcal{L}(\hat{\theta},z) \;+\; \lambda(\theta-\hat{\theta}),
\end{aligned} \tag{11}$$

where $G_{\hat{\theta}}$ is an approximation of the Gauss-Newton Hessian at $\hat{\theta}$.

Step 3: Solve for θ. Rearranging equation 11,

$$\big(G_{\hat{\theta}} + \lambda I\big)(\theta-\hat{\theta}) = -\epsilon\nabla_\theta\mathcal{L}(\hat{\theta},z), \tag{12}$$

and since $\mathcal{L}$ is convex as a function of the network outputs, then $G_{\hat{\theta}} \succeq 0$; adding λI with $\lambda > 0$ guarantees invertibility. Solving for θ therefore yields the unique minimizer

$$\hat{r}_{z,\mathrm{lin}}(\varepsilon) = \hat{\theta} - \big(G_{\hat{\theta}} + \lambda I\big)^{-1}\nabla_\theta\mathcal{L}(\hat{\theta},z)\,\epsilon, \tag{13}$$

as claimed. □

[2] With a mild abuse of notation, in this equation we denote with $f(z^{(i)},\theta)$ and $f(z^{(i)},\hat{\theta})$ the networks' predicted output distribution.

B KFAC APPROXIMATION OF THE INVERSE HESSIAN

Block-diagonal approximation. Computing the inverse of the Hessian $\boldsymbol{H}_{\theta^\star}$ at the trained parameters $\theta^\star$ is intractable for large models as, for m parameters, this operation requires $\mathcal{O}(m^2)$ storage and $\mathcal{O}(m^3)$ operations. To overcome this problem, we replace $\boldsymbol{H}_{\hat{\theta}}$ by the Gauss–Newton (Fisher) curvature and approximate the latter with Kronecker-Factored Approximate Curvature (K-FAC). Under this approximation, we treat the Hessian as block-diagonal matrix across projections, the individual linear weight matrices of the transformer. This avoids forming the dense $m \times m$ Hessian in its entirety, so reducing storage to a sum of per-projection blocks. We further restrict the approximation to the MLP projection weights $\{\theta_j\}_{j \in J}$ of each transformer block of the LLM, specifically the up- and down-projections, while attention, embedding, and normalization parameters are excluded. This is consistent with recent K-FAC formulations for modern architectures with linear weight sharing (Eschenhagen et al., 2023).

For each MLP projection j, the weight matrix $\theta_j \in \mathbb{R}^{o_j \times i_j}$, with i_j and o_j its input and output dimensions, admits a per-example gradient $g_j(z) \coloneqq \nabla_{\theta_j} \mathcal{L}(z, \hat{\theta})$. The corresponding block of the Hessian has size $(o_j i_j) \times (o_j i_j)$, which is still too large to store or invert directly. K-FAC addresses this by replacing it with a Kronecker product of two dense factors,

$$\hat{\boldsymbol{H}}_j \approx \boldsymbol{A}_j \otimes \boldsymbol{G}_j, \qquad \boldsymbol{A}_j \in \mathbb{R}^{i_j \times i_j}, \qquad \boldsymbol{G}_j \in \mathbb{R}^{o_j \times o_j}.$$

This reduces the per-projection storage cost from $\mathcal{O}(i_j^2 o_j^2)$ to $\mathcal{O}(i_j^2 + o_j^2)$. Crucially, A_j and G_j are full rather than diagonal matrices, so their Kronecker product retains within-projection parameter correlations that a diagonal approximation would discard (Martens & Grosse, 2015).

Estimation of the dense factors $\boldsymbol{A}_j, \boldsymbol{G}_j$. We estimate the retained factor from weight gradients using a gradient-Gram estimator, avoiding the need to buffer intermediate activations. Given the curvature dataset $\mathtt{D}_c$ (see Section 3.1, a curated dataset assumed in-distribution for the model's pretraining data), we normalise each per-example gradient $g_j(z) \coloneqq \nabla_{\theta_j} \mathcal{L}(z, \theta^\star)$ as $\tilde{g}_j(z) = g_j(z)/\|g_j(z)\|_F$ and average the corresponding Gram matrices:

$$\boldsymbol{A}_j = \frac{1}{|\mathtt{D}_c|} \sum_{z \in \mathtt{D}_c} \tilde{g}_j(z)^\top \tilde{g}_j(z), \qquad \boldsymbol{G}_j = \frac{1}{|\mathtt{D}_c|} \sum_{z \in \mathtt{D}_c} \tilde{g}_j(z) \tilde{g}_j(z)^\top.$$

In practice we accumulate these sums online, maintaining a running total and a sample counter over $\mathtt{D}_c$, and only divide by $|\mathtt{D}_c|$ once the factor is finalized for damping and inversion, so the stored curvature state does not grow with the number of curvature examples. For numerical stability during inversion, following the standard practice of regularizing Fisher-based curvature approximations (Eschenhagen et al., 2023; Lu & Armour, 2026), we damp the finalized factors as

$$\bar{\boldsymbol{A}}_j = \boldsymbol{A}_j + \gamma \frac{\operatorname{tr}(\boldsymbol{A}_j)}{h} \boldsymbol{I}_h, \qquad \bar{\boldsymbol{G}}_j = \boldsymbol{G}_j + \gamma \frac{\operatorname{tr}(\boldsymbol{G}_j)}{h} \boldsymbol{I}_h,$$

where $\gamma > 0$ is a damping coefficient and $\boldsymbol{I}_h \in \mathbb{R}^{h \times h}$ is the identity matrix.

One-sided simplification. To lower both storage and, more substantially, the cost of Cholesky inversion, we retain only the Kronecker factor of dimension h, the transformer's hidden dimension, and discard the factor of dimension d_{ffn}, the larger MLP intermediate dimension. Inversion cost scales as $\mathcal{O}(h^3)$ for the retained factor versus $\mathcal{O}(d_{\text{ffn}}^3)$ for the discarded one. In standard MLP architectures this coincides with discarding the larger of the two factors. For up-projections, where $i_j = h$, this is $\bar{\boldsymbol{A}}_j \in \mathbb{R}^{h \times h}$; for down-projections, where $o_j = h$, this is $\bar{\boldsymbol{G}}_j \in \mathbb{R}^{h \times h}$. The inverse curvature is then applied, one-sided:

$$\bar{g}_j(z) = \begin{cases} g_j(z) \bar{\boldsymbol{A}}_j^{-1} & \text{up-projection,} \\ \bar{\boldsymbol{G}}_j^{-1} g_j(z) & \text{down-projection,} \end{cases} \tag{14}$$

where $\bar{g}_j(z)$ has the same shape as θ_j, replacing the standard two-sided preconditioner $\bar{\boldsymbol{G}}_j^{-1} g_j(z) \bar{\boldsymbol{A}}_j^{-1}$.

Estimation of prompt influence scores. Substituting the damped, one-sided factors into the influence score reduces the computation of equation 2. For a chosen ℓ_p norm, the block-diagonal

structure of $\hat{\boldsymbol{H}}_{\theta^\star}^{-1}$ gives the tractable estimate

$$\left\|\mathbf{H}_{\hat{\theta}}^{-1}\nabla_\theta \mathcal{L}(\hat{\theta}, z)\right\|_p \;\approx\; \left(\sum_j \left\|\bar{g}_j(z)\right\|_p^p\right)^{\frac{1}{p}}, \tag{15}$$

where $\bar{g}_j(z)$ is the preconditioned gradient defined in equation 14. Here, the sum is taken for all MLP up- and down-projections of the model.

C Computational Cost of the K-FAC Curvature Computation

The detection results reported in Section 6.5 use the K-FAC configuration described in Section 3.2 and Appendix B. Table 4 reports the wall-clock time and peak GPU memory this configuration requires to compute the prompt influence score for a single prompt, averaged over 100 randomly sampled evaluation prompts per model, on the hardware described in Section 6. These numbers characterize the practical cost of applying CodeSIFT and complement the detection-accuracy results reported in Section 6.5.

Table 4: Wall-clock time and peak GPU memory for the K-FAC computation averaged over 100 prompts per model. Values are mean ± standard deviation.

Model	**Wall-clock (s)**	**Peak memory (GB)**
Granite-3B-Code-Instruct-2K	32.572 ± 0.134	30.857 ± 0.039
DeepSeek-Coder-6.7B-Instruct	36.776 ± 0.095	31.628 ± 0.000
Qwen2.5-Coder-7B-Instruct	39.017 ± 0.060	34.553 ± 0.052

D Datasets vulnerability coverage

Table 5 groups the malicious samples by vulnerability class, with representative CWE IDs for each. Samples from both the AuthSec and InfraCloud datasets are displayed in Figure 3-4 respectively.

E Hyperparameters for the Main Experiments

Unless otherwise noted, all experiments use the following fixed hyperparameters across models, datasets, and injection rates; Appendix F instead reports the effect of sweeping candidate-set size, sample count, and injection rate directly as figure axes.

We fix $\varepsilon = 10^{-3}$ and average $N = 25$ sampled responses per prompt when estimating $\mathrm{IF}_{p,\varepsilon}(z)$. K-FAC factors are damped with a base coefficient of 0.1, refined per-projection via a relative damping term of 0.1 and a damping floor γ; we use $\gamma = 10^{-3}$ for Granite-3B-Code-Instruct-2K and DeepSeek-Coder-6.7B-Instruct, and $\gamma = 10^{-2}$ for Qwen2.5-Coder-7B-Instruct, reflecting differences in curvature scale across architectures. The headline detection results use a fixed significance threshold of $\alpha = 0.01$. To assess calibration, Section 6.5 additionally sweeps the nominal significance level from 0.01 to 0.10 and reports the resulting empirical false positive rate.

F Additional experimental results

F.1 Overview across dataset size and sample count

Figures 5-6 and 7-8 plot AUROC as a function of dataset size, and separately as a function of the number of sampled completions per prompt, with all five detectors overlaid on the same axes. On AuthSec, CodeSIFT reaches near-ceiling AUROC with as few as 20 to 30 prompts in the candidate set, and its accuracy is essentially unaffected by how many completions are sampled per prompt, as few as 5 samples already suffice. On InfraCloud the same pattern holds at a lower ceiling, consistent

Table 5: Vulnerability classes in the malicious pool. Classes are listed in descending order of frequency within each family; each family totals 200 records. CWE identifiers are *representative*: each names the dominant weakness in its class, not a per-record label, and several classes span more than one entry. Rows marked −− aggregate a long tail of weaknesses that do not map cleanly to a single identifier.

Vulnerability class	**Rep. CWE**	**Records**
Authentication, authorisation, and session security		
Credential & secret exposure	CWE-200	23
Broken access control / IDOR	CWE-639	22
Federated auth / SSO flaws	CWE-287	19
Session management	CWE-384	19
JWT verification flaws	CWE-347	17
Business-logic flaws	CWE-841	17
Weak cryptography & randomness	CWE-327	16
Cookie security	CWE-1004	12
Brute-force & MFA bypass	CWE-307	9
Cross-site request forgery	CWE-352	8
Password storage and hashing	CWE-916	7
Timing & enumeration side channels	CWE-208	7
Password reset flows	CWE-640	6
Password policy	CWE-521	6
Other authentication failures	–	6
Race conditions	CWE-362	6
Subtotal		**200**
Infrastructure, cloud, and protocol exploitation		
Information disclosure	CWE-538	26

Figure 8: AUROC on InfraCloud as a function of number of sampled completions, for CodeSIFT (L_1, L_2) and the three static baselines jointly. Columns correspond to Granite-3B-Code-Instruct-2K, DeepSeek-Coder-6.7B-Instruct, and Qwen2.5-Coder-7B-Instruct.

F.2 Dataset size versus injection rate

Figures 9–11 report AUROC jointly as a function of dataset size and injection rate on AuthSec, and Figures 12–14 report the same on InfraCloud, one figure per model. CodeSIFT's accuracy increases along both axes, larger candidate sets and higher contamination rates each make detection easier, and the L_1 and L_2 variants behave near-identically throughout. Bandit stays largely flat around 0.5 to 0.6 regardless of either quantity, indicating no real dependence on contamination level or candidate set size, while Semgrep and the AST Taint Tracker decline as either axis grows, in several settings falling to an AUROC near zero at the largest dataset sizes and injection rates, that is, becoming more confidently wrong as more evidence accumulates rather than merely uninformative.

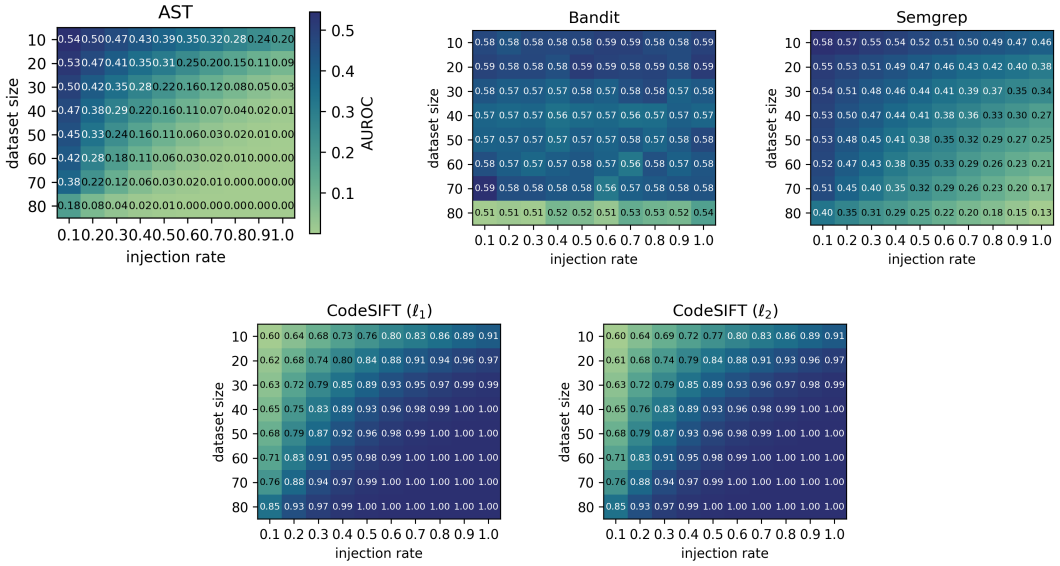

Figure 9: AUROC on AuthSec for Granite-3B-Code-Instruct-2K, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

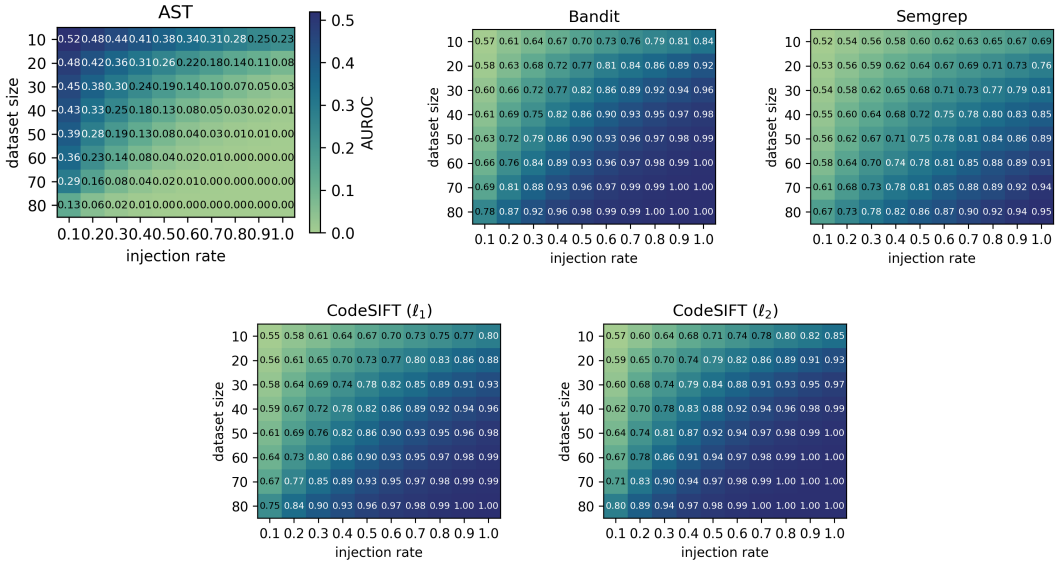

Figure 10: AUROC on AuthSec for DeepSeek-Coder-6.7B-Instruct, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

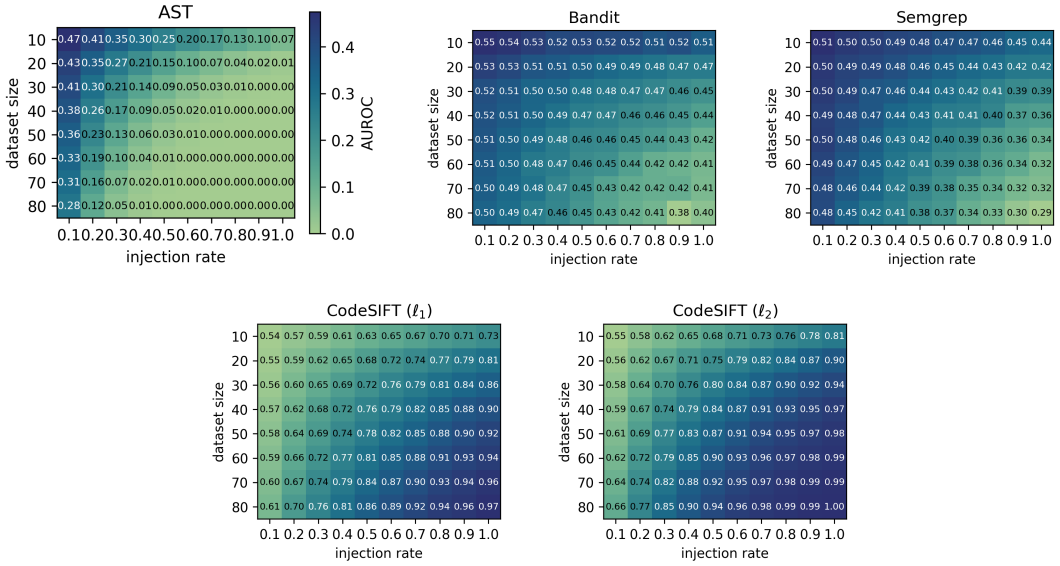

Figure 11: AUROC on AuthSec for Qwen2.5-Coder-7B-Instruct, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

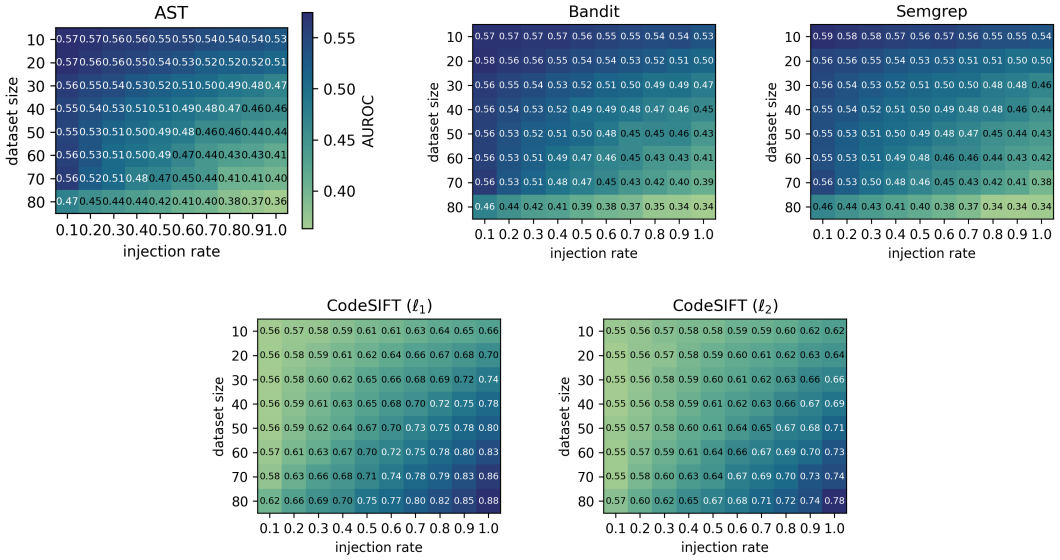

Figure 12: AUROC on InfraCloud for Granite-3B-Code-Instruct-2K, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

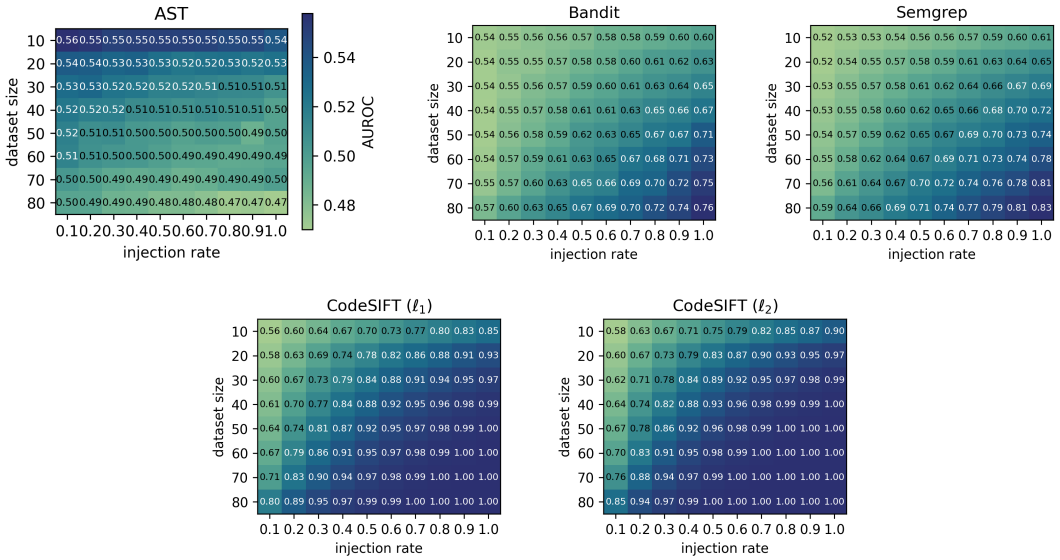

Figure 13: AUROC on InfraCloud for DeepSeek-Coder-6.7B-Instruct, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

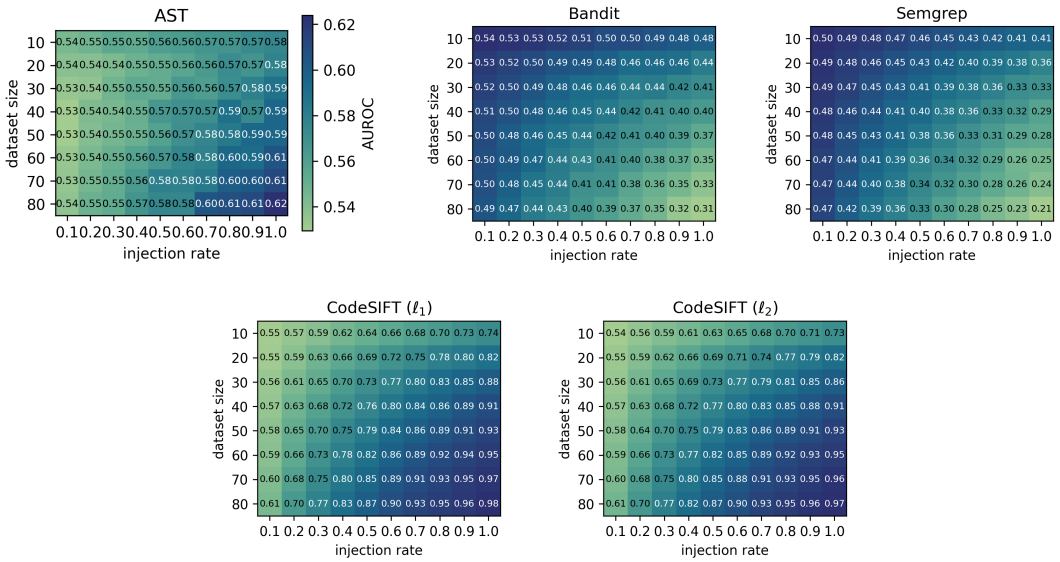

Figure 14: AUROC on InfraCloud for Qwen2.5-Coder-7B-Instruct, as a joint function of dataset size and injection rate, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row). CodeSIFT's AUROC increases monotonically along both axes, while the baselines remain largely flat or decline as either quantity grows.

F.3 Dataset size versus number of sampled completions

Figures 15–17 report AUROC jointly as a function of dataset size and the number of sampled completions per prompt on AuthSec, and Figures 18–20 report the same on InfraCloud, one figure per model, at a fixed injection rate. CodeSIFT's accuracy tracks dataset size almost exclusively, increasing steadily as the candidate set grows, and is essentially flat across the number of sampled completions, so the detector does not need many completions per prompt to work. The baselines show no clear structure along either axis, their AUROC fluctuates within a narrow band around chance regardless of how much data or how many completions are available.

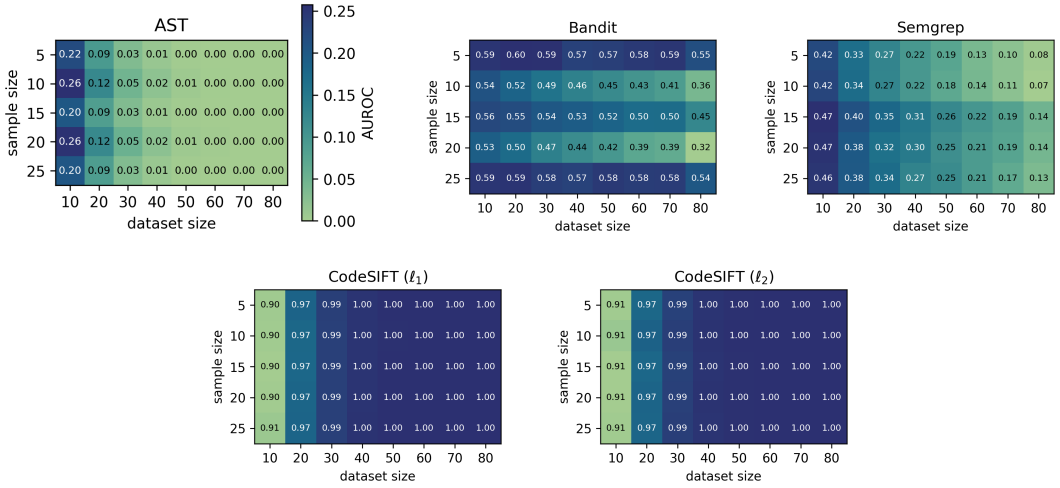

Figure 15: AUROC on AuthSec for Granite-3B-Code-Instruct-2K, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

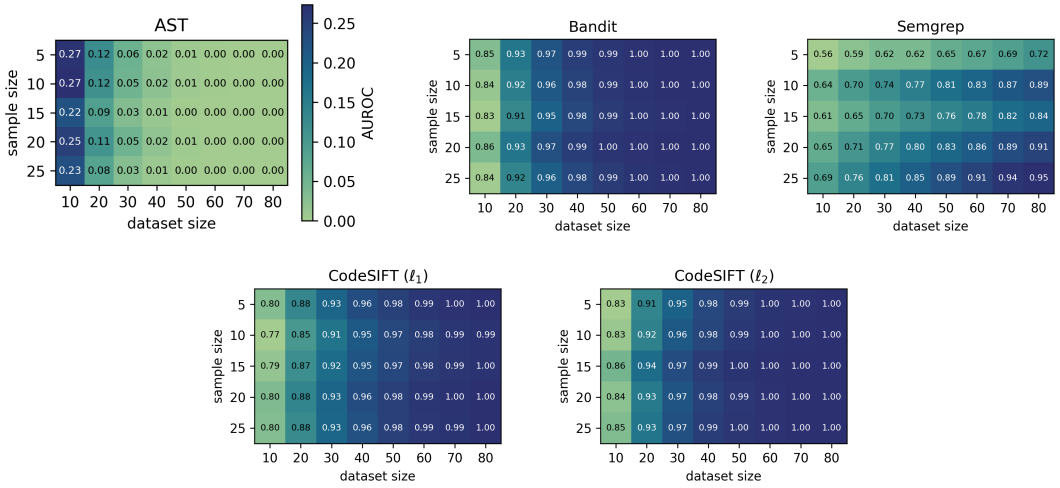

Figure 16: AUROC on AuthSec for DeepSeek-Coder-6.7B-Instruct, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

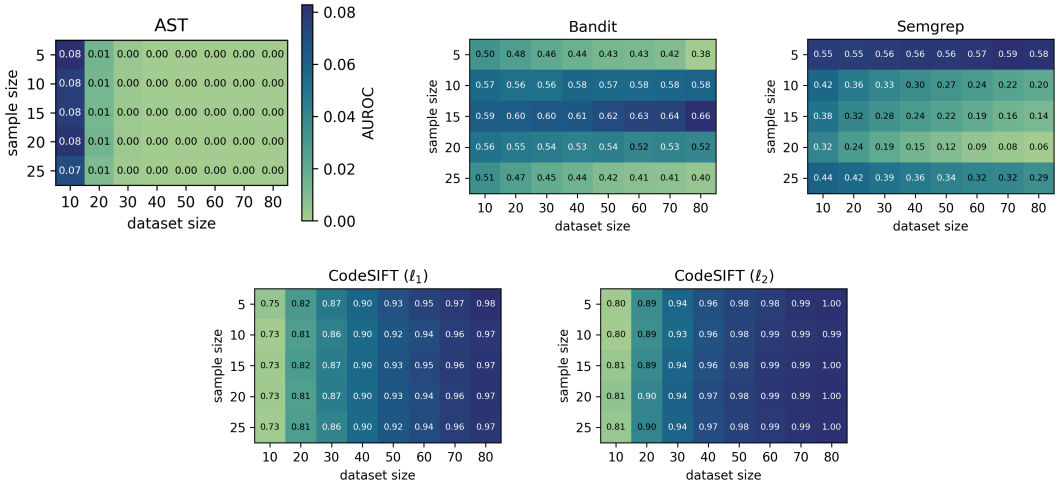

Figure 17: AUROC on AuthSec for Qwen2.5-Coder-7B-Instruct, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

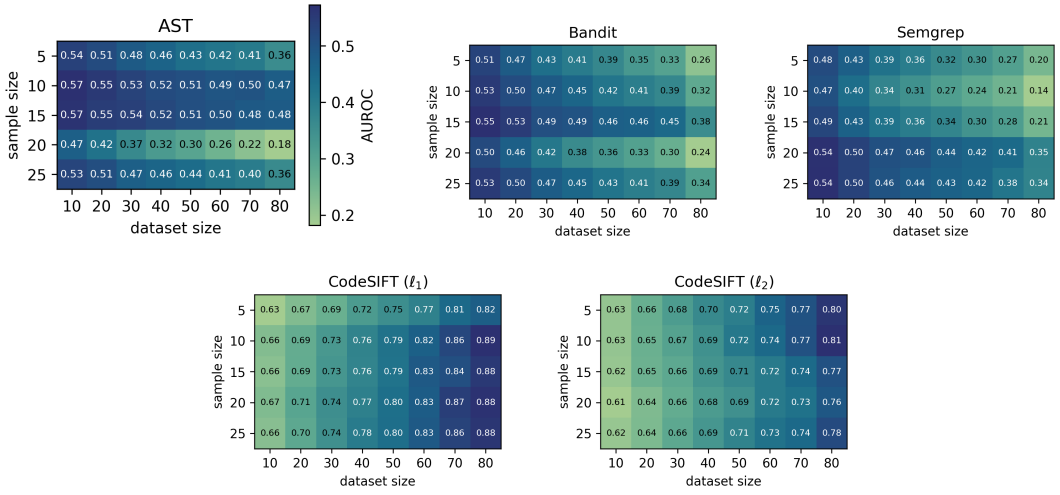

Figure 18: AUROC on InfraCloud for Granite-3B-Code-Instruct-2K, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

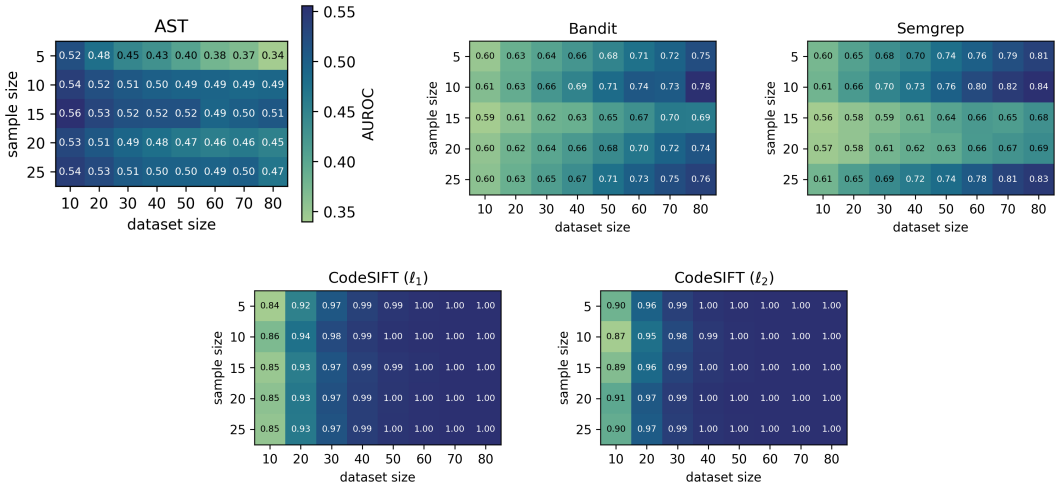

Figure 19: AUROC on InfraCloud for DeepSeek-Coder-6.7B-Instruct, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

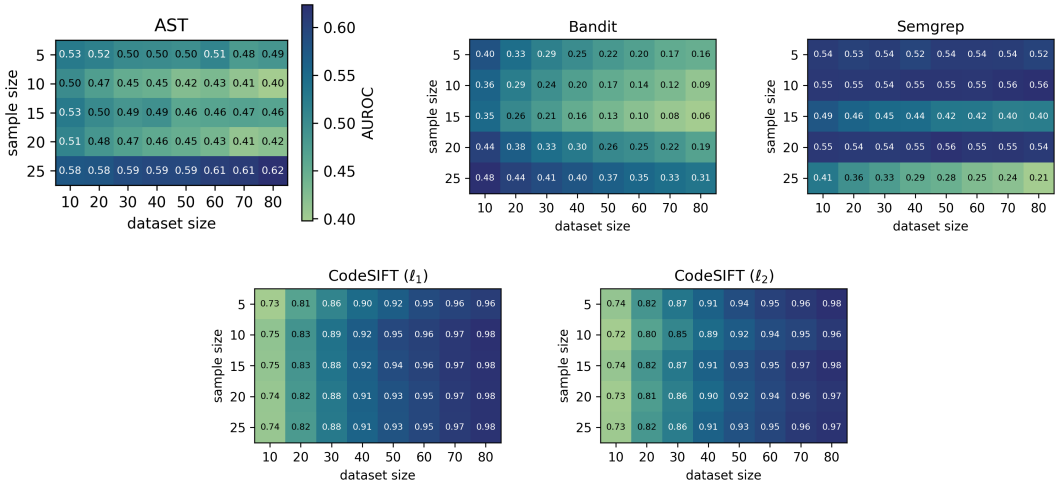

Figure 20: AUROC on InfraCloud for Qwen2.5-Coder-7B-Instruct, as a joint function of dataset size and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed injection rate. CodeSIFT's AUROC depends almost entirely on dataset size and is largely insensitive to the number of sampled completions, indicating the test is sample efficient. The baselines show no clear dependence on either axis.

F.4 Injection rate versus number of sampled completions

Figures 21–23 report AUROC jointly as a function of injection rate and the number of sampled completions per prompt on AuthSec, and Figures 24–26 report the same on InfraCloud, one figure per model, at a fixed dataset size. As in the previous sweep, CodeSIFT's accuracy tracks one axis almost exclusively, here the injection rate, increasing steadily as contamination grows, while remaining essentially flat across the number of sampled completions. The baselines again show no clear structure along either axis.

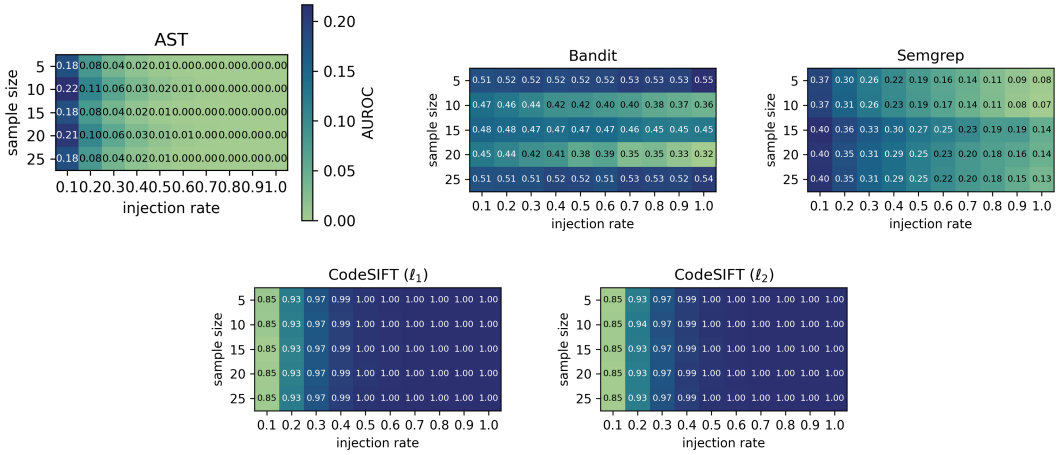

Figure 21: AUROC on AuthSec for Granite-3B-Code-Instruct-2K, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.

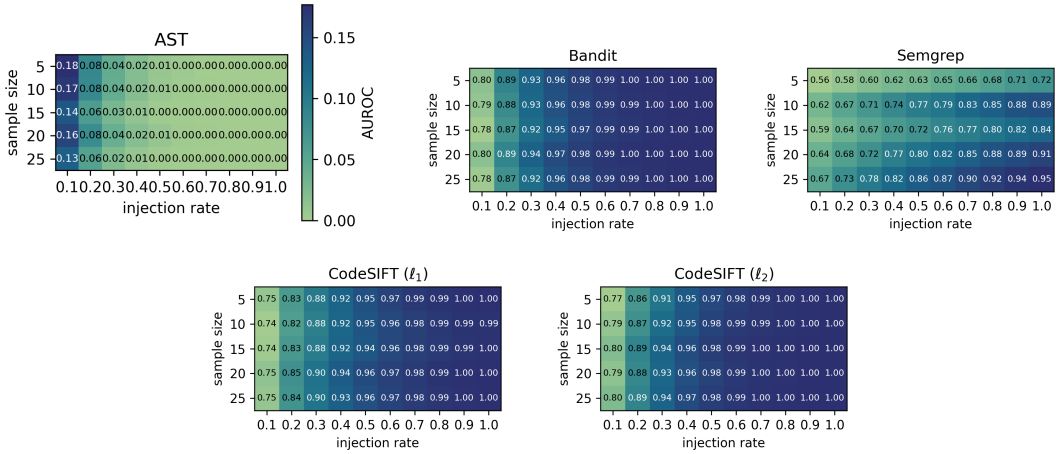

Figure 22: AUROC on AuthSec for DeepSeek-Coder-6.7B-Instruct, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.

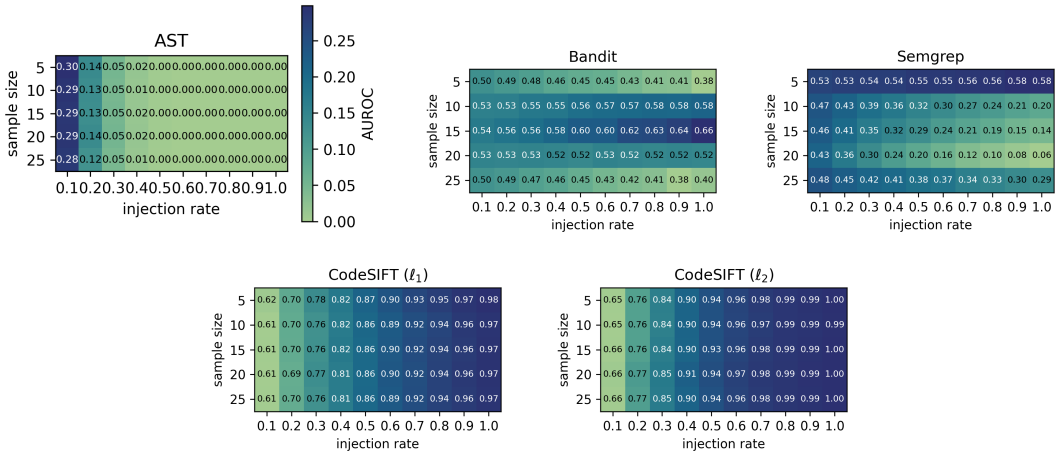

Figure 23: AUROC on AuthSec for Qwen2.5-Coder-7B-Instruct, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.

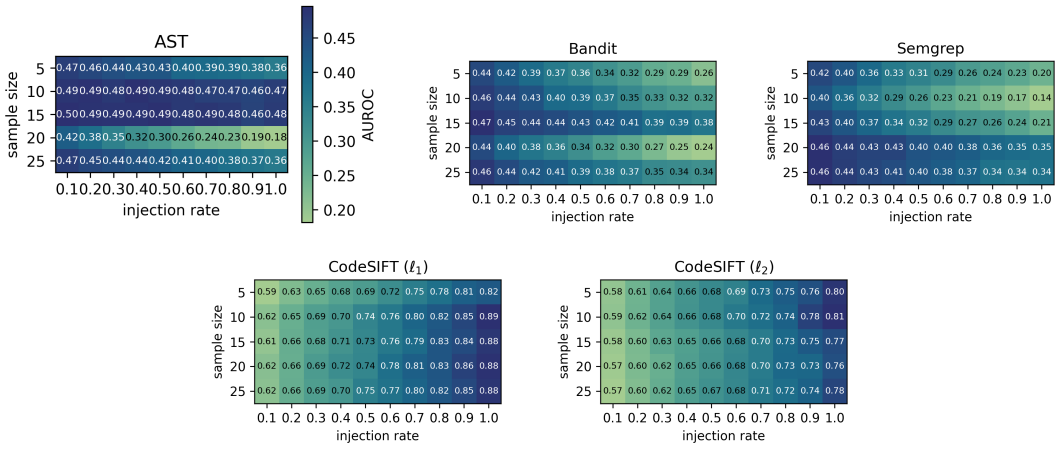

Figure 24: AUROC on InfraCloud for Granite-3B-Code-Instruct-2K, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.

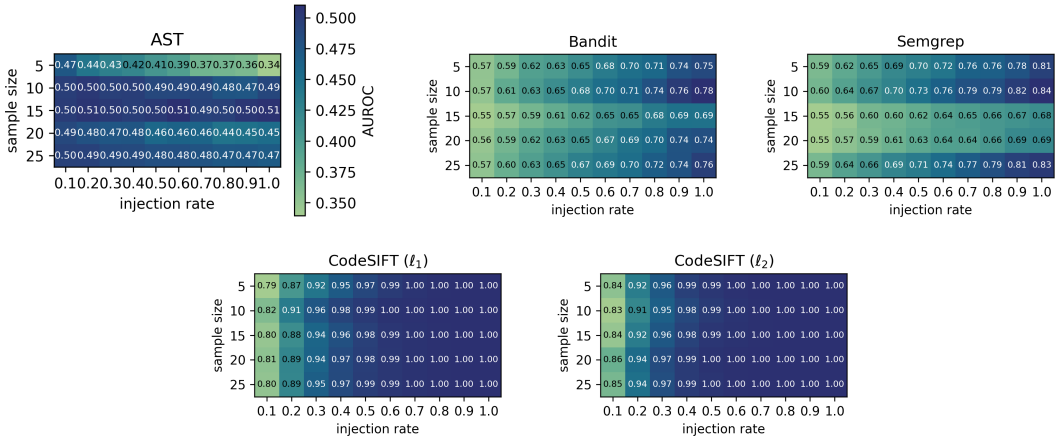

Figure 25: AUROC on InfraCloud for DeepSeek-Coder-6.7B-Instruct, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.

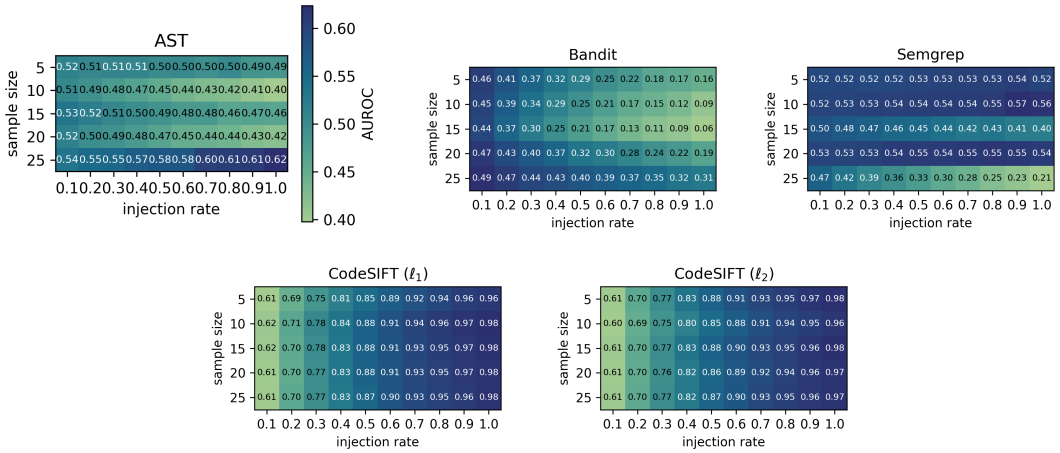

Figure 26: AUROC on InfraCloud for Qwen2.5-Coder-7B-Instruct, as a joint function of injection rate and number of sampled completions per prompt, for the three static baselines (top row) and CodeSIFT (L_1, L_2, bottom row), at a fixed dataset size. CodeSIFT's AUROC depends almost entirely on injection rate and is largely insensitive to the number of sampled completions. The baselines show no clear dependence on either axis.
