PRISONBREAK: JAILBREAKING LLMS WITH AT MOST TWENTY-FIVE TARGETED BIT-FLIPS

Anonymous authors
Paper under double-blind review

ABSTRACT

We present a new vulnerability in aligned large language models (LLMs): their alignment can be bypassed by flipping only a few bits in their parameter values. We exploit this vulnerability with an attack that jailbreaks billion-parameter LLMs with just 5–25 bit-flips—up to 40× fewer than prior bit-flip attacks. To this end, we present an efficient bit-selection algorithm that identifies critical bits for jailbreaks up to 20× faster than exhaustive strategies. Unlike prompt-based jailbreaks, our method directly alters model behavior in memory at inference time, enabling harmful outputs without any input-level modifications. We evaluate our attack on 10 LLMs, achieving attack success rates (ASRs) of 80–98% with negligible impact on model utility. We further demonstrate an end-to-end exploit via Rowhammer-based fault injection, reliably jailbreaking five models (69–91% ASR) on a GDDR6 GPU by exploiting just *two* vulnerable physical bit locations. Moreover, bit-flip locations identified in one fine-tuned model transfer to others that share the same pre-trained LLMs, demonstrating the black-box exploitability in standard pretraining-then-finetuning paradigms. We evaluate potential countermeasures and find that our attack remains effective against defenses at various stages of the inference pipeline.

1 INTRODUCTION

Deep neural networks are vulnerable to parameter corruption, which adversaries can exploit to trigger undesirable behaviors. These include severe performance degradation (Hong et al., 2019; Rakin et al., 2019), targeted misclassifications (Rakin et al., 2022b; Bai et al., 2023), backdoor injections (Cai et al., 2024; Zheng et al., 2023), and confidentiality risks such as model extraction (Rakin et al., 2022a). These attacks exploit the vulnerability through practical fault-injection techniques (Kim et al., 2014b) that cause bit-wise errors in the memory representation of model parameters.

Most prior work targets CNNs in classification tasks (Cai et al., 2024; Yao et al., 2020; Rakin et al., 2019; 2022b; Bai et al., 2023; Chen et al., 2021a; Tol et al., 2023). While valuable, these studies overlook the vulnerability of language models—which are now central components of many modern AI systems—to parameter corruption. A small number of recent works have examined attacks on language models that degrade performance (Das et al., 2025; Xu et al., 2025) or induce attacker-chosen outputs (Cai et al., 2021). However, it remains unclear whether such models are susceptible to more severe attacks that could induce unsafe behaviors and harm downstream users.

A particularly compelling and previously unexplored scenario is whether an adversary can remove a language model's alignment—i.e., induce a *jailbreak*—through minimal bit-wise corruptions to its parameters. In this paper, we study this vulnerability by asking: *How vulnerable is the refusal behavior of aligned LLMs to bit-flips induced by practical fault-injection attacks?* Once exploited at runtime, such attacks jailbreak a target model in memory for the lifetime of the process. Unlike prompt-based jailbreaks (Zou et al., 2023; Liu et al., 2024), which leverage input-level perturbations, our attack directly corrupts model parameters to provoke harmful responses.

Contributions. We first introduce an efficient (offline) procedure for identifying parameter bit locations whose flipping induces jailbreak. Combined with the software-induced fault-injection attack, Rowhammer (Kim et al., 2014b), this enables our attack, PRISONBREAK. Our approach employs a progressive bit-search, which iteratively identifies a sequence of target bits to flip based on a gradient-based scoring scheme that leverages our novel jailbreak objective. We also present speed-up techniques to address the computational burden of searching across billions of parameters.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

We evaluate PRISONBREAK on 10 open-source language models. We achieve attack success rates (ASRs) of 80–98% using only 5–25 targeted bit-flips, while reducing the bit-search cost by up to $\sim$20$\times$ with negligible impact on model utility. We also show that bit-flips transfer across models sharing the same architectures and pre-training data; thus, full knowledge of model parameters is not strictly necessary. To demonstrate real-world feasibility, we conduct an end-to-end Rowhammer-based fault-injection attack on an NVIDIA A6000 GPU. As our target DRAM exhibits up to $10^5\times$ fewer exploitable bit-flips than prior work, we optimize our bit-search to select only bits flippable at the hardware-level. Using this approach, we successfully jailbreak five models with 69–91% ASR.

To understand this vulnerability, we conduct several analyses. Our structural analysis reveals that certain model components, e.g., exponent bits and value projections, are disproportionately vulnerable. In our behavioral analysis in the activation space, we show that PRISONBREAK works differently from existing jailbreaks, as we do not observe refusal suppression. We also explore potential countermeasures, highlighting their applicability and limitations. Our findings highlight a practical threat to the LLM ecosystem, underscoring the need for research to protect them from bit-flip attacks.

2 BACKGROUND AND RELATED WORK

Aligning and jailbreaking LLMs. Malicious users can exploit LLMs' capabilities to produce biased, deceptive, or otherwise harmful content (Weidinger et al., 2022; 2021). In response, several techniques try to ensure these models generate outputs *aligned with human values*, e.g., supervised fine-tuning (SFT) (Touvron et al., 2023a), reinforcement learning with human feedback (RLHF) (Ouyang et al., 2022), and direct preference optimization (DPO) (Rafailov et al., 2023). Aligned models (Touvron et al., 2023b; Dubey et al., 2024; Yang et al., 2024) are trained to *refuse* harmful queries.

Recent works study the vulnerability of aligned LLMs to *jailbreaking* attacks, which induce models to generate harmful responses. As these models are accessible to any user prompt, most jailbreaks are *prompt*-based (Zou et al., 2023; Liu et al., 2024; Geisler et al., 2024; Yu et al., 2023), crafting inputs that bypass alignment by compelling models to respond to queries they would otherwise refuse. Recently, several works have also presented *parameter*-based jailbreaks which tune billions of parameters on harmful text to remove alignment (Yang et al., 2023; Arditi et al., 2024). In contrast, we exploit Rowhammer (Kim et al., 2014b) to flip at most 25 bits in a model to jailbreak it at runtime.

Half-precision floating-point numbers. Modern computer systems use the IEEE 754 floating-point format to represent model parameters. Unlike conventional models that typically use single-precision (32-bit), language models with billions of parameters are commonly deployed in *half-precision* (16-bit), with a sign bit, 5 exponent bits, and 10 mantissa bits to reduce memory footprint. For instance, in half-precision, -0.1094 is represented as -1.75×2^{-4}, where -1 is the sign, 1.75 is the mantissa, and -4 is the exponent. Here the exponent bits play a significant role: flipping a bit in the mantissa induces a marginal change to -1.875×2^{-4}, whereas a bit-flip in the exponent can shift the value to -1.75×2^{12}. Our attacker favors this insight to jailbreak a model with a few bit-flips.

Rowhammer is a practical, software-based fault injection attack (Kim et al., 2014b). It exploits DRAM disturbance errors by repeatedly accessing rows (i.e., aggressors) to accelerate charge leakage in adjacent rows, thereby causing a bit-flip. Recent works have shown numerous Rowhammer exploits on both CPUs (Kwong et al., 2020; Seaborn & Dullien, 2015; Jattke et al., 2024; Frigo et al., 2020; Jattke et al., 2022; Kogler et al., 2022; Hassan et al., 2022; Olgun et al., 2024) and GPUs (Lin et al., 2025; Hu et al., 2026; Wan et al., 2026; Lin et al., 2026a;b). Rowhammer exploits have also targeted neural networks to achieve performance degradation (Rakin et al., 2019; Yao et al., 2020; Das et al., 2025; Xu et al., 2025), targeted misclassification (Rakin et al., 2022b; Bai et al., 2023; Cai et al., 2021), backdooring (Rakin et al., 2020; Zheng et al., 2023; Cai et al., 2024; Chen et al., 2021a; Tol et al., 2023; Li et al., 2025a), and model extraction (Rakin et al., 2022a). Our work advances this direction by presenting the first attack that exploits Rowhammer to jailbreak language models.

3 THREAT MODEL

Setting. We consider an adversary aiming to jailbreak a safety-aligned LLM by tampering with its parameters in memory at *runtime*. The victim serves the model on a GPU that also runs an isolated, attacker-controlled workload, which is possible via widely deployed features such as time-sliced GPU

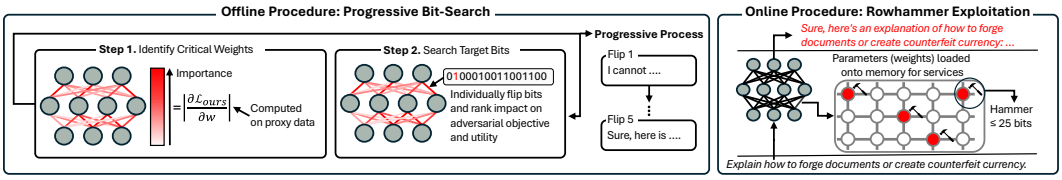

Figure 1: **PRISONBREAK workflow.** An illustration of the steps in our offline and online procedures.

sharing (NVIDIA; Geller; Adrounie et al.). This assumption aligns with prior GPU Rowhammer work (Lin et al., 2026a; 2025; Wan et al., 2026; Lin et al., 2026b).

For our end-to-end demonstration (§6), we assume ECC is disabled and GPU memory is managed by the RAPIDS Memory Manager (RMM) (RAPIDS AI), following prior work (Lin et al., 2025). This ECC configuration is plausible: enabling ECC reduces usable memory and incurs a performance cost on GDDR6 GPUs (Lin et al., 2025; 2026b), and we identified two cloud providers (names omitted for safety) offering ECC-disabled GDDR6 GPU instances. Furthermore, these assumptions may be relaxed in other realizations: prior work demonstrates attacks on ECC-protected GDDR6 (Lin et al., 2026a) and on systems using the CUDA allocator (Hu et al., 2026). We also assume GPU memory swapping (NVIDIA Run:ai Docs) to reuse the few suitable vulnerable physical cells found on our GPU. With more suitable cells (e.g., as found in Lin et al. (2026a)), this feature may be unnecessary.

Knowledge. Our primary setting assumes a white-box attacker that knows the target model's architecture and parameters, which is feasible if the victim deploys a public checkpoint (a common practice (Meta, 2024)). In §5.3, we additionally evaluate the effectiveness of a black-box attacker that transfers bit-flips between models sharing key components such as pre-training data. The attacker has no access to the victim process or deployment pipeline and requires no training data.

Capabilities. The attacker exploits Rowhammer (Kim et al., 2014b) to induce targeted bit-flips in memory. They can *co-locate* a process alongside the victim's process on the same GPU and execute CUDA kernels with *user-level privileges*. The host OS is uncompromised, and process isolation is enforced. We assume the attacker can reverse-engineer GPU DRAM address mappings and place target weights at desired locations using techniques established in prior work (Lin et al., 2025). While we focus on GPUs, our attack applies to other vulnerable memories (e.g., DDR4 (Jattke et al., 2022)).

4 PRISONBREAK

We present PRISONBREAK, our bit-flip attack to jailbreak LLMs. Figure 1 illustrates its workflow.

❶ **Offline procedure.** The attacker identifies *target bit* locations in the victim model's memory using a *progressive bit-search*: critical weights are ranked by their jailbreaking effectiveness, then bits within them are flipped one at a time in isolation, with the most effective flip retained at each step. The attacker repeats for a fixed number of iterations. PRISONBREAK supports both *hardware-agnostic* search (assumes any bit is flippable) and *hardware-aware* search (restricted to bits flippable on a profiled DRAM module), depending on DRAM vulnerability. Both modes are detailed in §4.2.3.

❷ **Online procedure.** After identifying target bits, PRISONBREAK jailbreaks the victim LLM by flipping them. Following our threat model in §3, this exploitation is accomplished using advanced Rowhammer techniques, including memory templating (Pessl et al., 2016) and massaging (Kwong et al., 2020), and Rowhammer attacks (Frigo et al., 2020; Jattke et al., 2022; 2024) that bypass in-DRAM target row refresh and induce precise bit-flips.

4.1 DESIGN CHALLENGES AND OUR APPROACH

Our attack is designed to address three major challenges: C_1 **High computational costs:** LLMs are significantly larger than models in prior work (Zheng et al., 2023; Cai et al., 2024; Yao et al., 2020; Cai et al., 2021), necessitating several search-space reductions. C_2 **Preserving model quality:** Optimizing only for affirmative prefixes (as in prompt-based jailbreaks) leads to low-quality outputs, so we extend our objective to include harmful continuations and filter out destructive bits. C_3 **Rowhammer exploitability:** GPUs exhibit orders-of-magnitude fewer flippable bits than CPU DRAM (Lin et al., 2025), so we constrain our search accordingly.

4.2 Offline Profiling of Target Bits

4.2.1 Our Jailbreaking Objective

PrisonBreak uses a progressive bit-search, identifying critical weights and target bits based on gradients computed with respect to an attack objective. Prior BFA objectives—primarily spanning utility degradation (Rakin et al., 2019; Yao et al., 2020), targeted misclassification (Rakin et al., 2022b; Bai et al., 2023), and backdoor injection (Cai et al., 2024; Rakin et al., 2020)—were developed for classification, where success amounts to flipping a single label. Jailbreaking, in contrast, requires steering generation toward long-form, harmful content, motivating our proposed objective.

Limitations of employing prior objectives. As described in C_2 in §4.1, the attack objective proposed in prompt-based jailbreaks (Carlini et al., 2023; Zou et al., 2023; Liu et al., 2024)—which makes the target model begin its response with *affirmative tokens*—results in two failure modes: Overfitting: The model excessively overfits to affirmative tokens, resulting in repetitive outputs; Backtracking: The response begins with affirmative tokens but quickly backtracks and refuses. Table 1 provides examples illustrating responses generated using only the prior work's objective in PrisonBreak. Despite beginning with an affirmative response, these outputs have *low fidelity*.

Improving our attack's fidelity. We hypothesize that lower fidelity arises because the objective focuses solely on affirmative tokens, neglecting actual harmful content. We address this by designing an objective that considers both. This requires *oracle harmful responses*—plausible excerpts of harmful content the model might produce if non-aligned—which we generate using an open-source unaligned model (HuggingFace, 2024): we collect 41 harmful queries from the HarmBench (Mazeika et al., 2024) "val" set and prompt-engineer responses to begin with affirmative tokens followed by harmful content. We refer to this collection of query–response pairs as our *proxy dataset*.

Our jailbreaking objective is defined to maximize the likelihood of a target model responding with both an affirmative response *and* explicitly harmful content, as follows:

$$\mathcal{L}_{JB} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{k=1}^{m} e^{-\left(\frac{k-1}{m-1}\right)} \log f_\theta(y_k|s_{k-1}),$$

where (x, y) is a prompt-target pair from our proxy dataset, N is the size of the dataset, $s_{k-1} = (x_1, \ldots, x_n, y_1, \ldots, y_{k-1})$ is the tokens up to position $k-1$, $f_\theta(y_k|s_{k-1})$ is the probability of f_θ generating token y_k, and m is the number of tokens in y. Our loss combines a standard cross-entropy term (dark red) with a *weighting* term (blue) that emphasizes earlier tokens, since the model must first produce affirmative tokens to make harmful continuations likely. Weights decay smoothly along the sequence (e.g., for m = 20, the first, tenth, and last tokens receive weights of 1, 0.623, and 0.368).

4.2.2 Identifying Critical Weights

Next, we search for *critical weights* whose bit-level manipulation can lead to jailbreaking.

Gradient-based ranking. A natural choice for gauging a weight's importance is to consider the magnitude of its gradient with respect to our attack objective, i.e., $\mathcal{I} = |\nabla_\theta \mathcal{L}_{JB}|$. A larger gradient magnitude indicates that modifying the weight will induce a larger change in $\mathcal{L}_{JB}$.

Parameter-level speed-up techniques. Following prior work (Yao et al., 2020; Cai et al., 2024; Rakin et al., 2019), we perform gradient-based ranking independently in each layer to parallelize computation. However, with billions of weights per LLM, searching over all layers becomes intractable, so we apply two further reductions (C_1). First, we skip layers that our bit-search never selects in preliminary experiments—normalization, embedding, and unembedding—reducing the

search space by ∼20%. Second, we restrict inspection to the top-k critical weights per layer; we set $k = 100$, which achieves 80–98% ASR across all evaluated models, though smaller values suffice (e.g., in Appendix H we show $k = 10$ yields 73.6–89.3% ASR).

4.2.3 SELECTING TARGET BITS

We select target bits based on importance scores that capture jailbreaking success and generation quality (C2). We also develop bit-level speed-up techniques to accelerate selection (C1). Moreover, if an adversary has profiled a specific DRAM module, they can assess whether chosen bits are flippable with Rowhammer. If not, those bits are excluded from search (C3). We first show the procedure for a hardware-agnostic adversary and then show how the hardware-aware one can skip non-flippable bits.

❶ **Rank the bits by the jailbreak score.** We rank all identified bits based on the jailbreaking score:

Definition 4.1 (**Jailbreaking Score**). Given a bit $b_i \in \mathbf{B}$ and the loss of a model f computed using our jailbreaking objective $\mathcal{L}_{JB}$, the jailbreaking score $\mathcal{S}_i$ is defined as:

$$\mathcal{S}_i = \mathcal{L}_{JB}(f_i', \cdot) - \mathcal{L}_{JB}(f, \cdot).$$

where f_i' is the model with a bit b_i flipped, and $\mathbf{B}$ represents all bits in the critical weights. The attacker computes this score for each bit and ranks all bits in ascending order.

❷ **Selecting a bit based on the utility score.** Our preliminary attack, which uses only the jailbreaking score to select target bits, often reduces the model's ability to produce coherent, high-quality answers. To measure the likelihood of a bit-flip degrading utility, we present the utility score.

Definition 4.2 (**Utility Score**). Given a bit $b_i \in \mathbf{B}$ and the model f, the utility score $\mathcal{U}$ is:

$$\mathcal{U}(f, D_c) = \tfrac{1}{N_c} \textstyle\sum_{i=1}^{N_c} \mathcal{L}_{ce}(f, x_i, y_i),$$

where D_c is a clean dataset to evaluate f's utility, $\mathcal{L}_{ce}$ is the cross-entropy loss, and $(x_i, y_i)|_{i=1}^{N_c}$ are the prompt–target pairs. We build D_c by sampling 100 prompts from ALPACA (Taori et al., 2023). For each prompt x_i, we generate y_i from the unmodified target model using greedy decoding.

Recall that we have a sorted list of bits ranked by the jailbreaking scores. For each bit, we compute the change in the utility score $\Delta\mathcal{U} = \mathcal{U}(f_i', D_c) - \mathcal{U}(f, D_c)$, where f_i' is the model with the chosen bit flipped and $\mathcal{U}(f, D_c)$ is the utility score of the original model. We then define a threshold τ, where if $\Delta\mathcal{U} < \tau$, we flip the chosen bit and continue the progressive search; otherwise, we move to the next bit in the list until we find a suitable one. In our attack evaluation, we set τ to 0.01.

Bit-level speed-up techniques. Even with parameter-level reductions, examining all 16 bits per critical weight is intractable; e.g., bit-search on LLAMA2-7B would require ∼8 days on 4× H100 GPUs. We apply three further reductions based on properties of each weight w. First, we skip bits whose flip yields $\text{sign}(\Delta w) = \text{sign}(\nabla w)$, since these increase the loss. Second, we restrict to the three most significant exponent bits, as we find that they are the only flips large enough to induce noticeable changes in model behavior. Third, we restrict to $0 \to 1$ flips, as most weights have small magnitudes, which cause $1 \to 0$ flips to have negligible effect. Together, these reduce the average number of bits examined per weight from 16 to ∼1, cutting the above search time to ∼0.5 days.

❸ **Skipping non-flippable bits.** The hardware-aware attacker knows the offsets within the DRAM's physical pages, along with the flip directions that Rowhammer can induce (0→1 or 1→0). As such, they select *only* bits that match the offset and flip direction of *at least one* vulnerable cell.

5 EVALUATION

We evaluate PRISONBREAK's effectiveness in jailbreaking LLMs using our hardware-agnostic search; in §6, we evaluate our hardware-aware search (and end-to-end effectiveness) on a real GPU.

5.1 EXPERIMENTAL SETUP

Models. We evaluate 10 open-source LLMs, shown in Table 2. Model parameters are represented as half-precision floating-point numbers (`float16`), with sizes ranging from 1.5–70 billion. We intentionally select models with different combinations of alignment algorithms. All experiments use

*Due to the scale of LLAMA3-70B, we set k to 10 for the bit-flip attacks to reduce search time; for other models, $k = 100$.

Table 3: **PRISONBREAK effectiveness.** The attack success rate (**ASR**) and average accuracy (**Acc.**) for each attack. **ΔAcc.** denotes the %-point change from clean performance. For parameter-based attacks, we also report the number of modified parameters (**ΔP**). The best ASR per model is **bolded**.

each model's default chat template. While we focus on dense LLMs in `float16` format, we evaluate more datatypes in Appendix C and a mixture-of-expert architecture in Appendix L.

Metrics. To evaluate attack effectiveness, we use HARMBENCH (Mazeika et al., 2024). We use the full test set in the Standard Behaviors split, which consists of 159 prompts, and use the provided classifier to judge whether the response was harmful; we evaluate an additional harmful prompt source in Appendix I and additional judges in Appendix J. We then report the percentage of harmful responses as the attack success rate (ASR). We evaluate model utility using TINYBENCHMARKS (Polo et al., 2024), reporting the average accuracy across all tasks (Acc.).

Model Family	# Parameters	Alignment
VICUNA Chiang et al. (2023)	7B, 13B	SFT

QWEN2 INSTRUCT Yang et al. (2024)	1.5B, 7B	SFT, RLHF, DPO

Table 2: **Model families.** Parameter counts and alignment algorithms of the model families we use.

Baselines. We compare against three baselines. **GCG-M** (Zou et al., 2023) is a prompt-based jailbreak that learns a universal adversarial suffix; we use HARMBENCH's implementation. **Ortho** (Arditi et al., 2024) is a parameter-based jailbreak that estimates a "refusal direction" in activation space and ablates it from the residual stream; we use the official implementation. **Baseline BFA** is an adaptation of prior bit-flip attacks (Yao et al., 2020; Rakin et al., 2019); we remove PRISONBREAK's novel components (our proxy dataset, utility score, and weighted loss) but retain the speed-up techniques.

5.2 PRISONBREAK EFFECTIVENESS

We first evaluate the effectiveness of attacks across open-source LLMs. Here, we test the *ideal* attack conditions by assuming all target bits are flippable via Rowhammer.

Results. Table 3 summarizes our results. We test each attack and report the ASR and change in Acc. (ΔAcc.). We do not report ΔAcc. for GCG-M, as prompt-based attacks are not applicable to benign queries. For parameter-based attacks, we report the number of modified parameters (ΔP).

PRISONBREAK outperforms all baseline attacks with an average ASR of 89.6%. Our attack offers distinct advantages over GCG: it enables permanent runtime jailbreaking, requires no input modifications, and achieves an average 1.73× higher ASR. Notably, our attack improves over BASELINE BFA by an average ASR of 22.3. By extending the context in the target responses and avoiding destructive bit flips, we obtain much higher-quality target bits. The attack performing closest to ours is ORTHO, with comparative ASRs. However, it modifies 0.7–23.4 billion parameters, making it practically infeasible for Rowhammer. Surprisingly, we are able to break safety alignment by modifying only 5–25 parameters (i.e., 5–25 bits), a reduction of 10^7–$10^9\times$ compared to ORTHO.

Model size does not matter, but alignment algorithm does. While prior work suggests that larger models are more resilient to bit-flips due to redundant parameters (Yao et al., 2020; He et al., 2020; Bai et al., 2023; Rakin et al., 2022b), we observe no clear relationship between model size and ASR: as parameters scale (1.5→7/8→13→70B), ASR slightly decreases for VICUNA (93.1→90.6%), holds steady for LLAMA2, and increases for LLAMA3 and QWEN2 (80.5→98.1%). Alignment, in contrast, does appear to affect resilience. VICUNA (SFT only (Touvron et al., 2023a;b)) requires 5–20 bit-flips

Source Model	Target Model	Architecture	Pre-Training	Fine-Tuning	Post-Training Alignment	Target→Target		Source→Target	
						ASR	ΔAcc.	ASR	ΔAcc.

VICUNA-7B-V1.5	LLAMA2-7B	✓	✓	✗	✗	86.79	-1.92	49.06	-1.85
VICUNA-7B-V1.3	VICUNA-7B-V1.5	✓	✗	✗	✗	93.08	-2.52	19.50	-1.07
QWEN2-1.5B	QWEN2-7B	✗	✓	✓	✓	93.08	-1.01	16.35	+0.91

Table 4: **Black-box results.** The ASR and ΔAcc. when flipping bits found directly on the *target* model (**Target→Target**) vs. using bit-flips found on a different *source* model (**Source→Target**).

to jailbreak, while LLAMA, TULU, and QWEN (which additionally apply RLHF (Ouyang et al., 2022; Dai et al., 2024), DPO (Rafailov et al., 2023), or both) require 13–25. Despite the substantial training costs of these alignment methods, our attack overcomes them with only a handful more bit flips.

Our attack preserves model utility. Maintaining generation quality is important: a degraded model lets the victim easily detect anomalies and reload from disk. PRISONBREAK causes minimal degradation (-2.3%), versus $\sim$7$\times$ higher loss for BASELINE BFA (-15.5%), which selects destructive flips due to the lack of utility score. We see a slightly higher loss than ORTHO, as PRISONBREAK concentrates behavior changes in $\leq$25 weights rather than distributing them across $\geq$0.7B parameters.

5.3 EXPLOITABILITY UNDER BLACK-BOX SETTINGS

We evaluate PRISONBREAK in black-box scenarios where the attacker lacks access to the target model's parameters. The attacker exploits the standard *pretraining-then-finetuning* paradigm: many practitioners open-source pre-trained LLMs for others to fine-tune (Dubey et al., 2024; Touvron et al., 2023b; Yang et al., 2024; Team et al., 2024), producing model families that share architectures, pre-training data, or alignment procedures. An attacker with white-box access to an open-source **source** model can identify bit-flips and transfer them to a **target** model without accessing its parameters.

Table 4 reports our results. We select source–target pairs from §5.2 and also include the SFT-only checkpoint of TULU3-8B to isolate the impact of post-training alignment; in Appendix F, we evaluate 11 additional source–target model pairs, including 4 new targets. **Bit-flip locations transfer effectively when source and target share key stages of the LLM development pipeline.** TULU3-8B-SFT→TULU3-8B, differing only in post-training alignment, achieves the highest transferability (70.4% ASR, 81% of white-box effectiveness). VICUNA-7B-V1.5→LLAMA2-7B, sharing architecture and pre-training, reaches a significant 49.1% ASR. Transfer degrades substantially when source and target diverge in architecture or training. VICUNA-7B-V1.3→VICUNA-7B-V1.5 (same architecture, all training stages differ) yields 19.5% ASR; QWEN2-1.5B→QWEN2-7B (architectural differences) yields 16.4%. These cases produce substantial divergence in learned parameters, reducing the effectiveness of transferred bit-flips.

6 END-TO-END ROWHAMMER EXPLOITATION

We demonstrate the practicality of PRISONBREAK end-to-end by jailbreaking LLMs on an NVIDIA A6000 GPU with 48GB GDDR6 DRAM; we also target an NVIDIA A5000 in Appendix M.4. To our knowledge, this is the first *targeted* Rowhammer-based bit-flip attack on a GPU. The key challenge is that our GPU exhibits 10^3–$10^5\times$ fewer flippable bits than the CPU DRAM exploited in prior work (Yao et al., 2020; Rakin et al., 2022a; Tol et al., 2023; Cai et al., 2024; Li et al., 2025a).

Setup. Per our threat model (§3), the attacker is co-located with the victim on a time-sliced GPU with memory swapping (NVIDIA Run:ai Docs), managed by RMM (RAPIDS AI). Offline, we profile the DRAM and apply our hardware-aware search (§4.2.3). Profiling across eight banks yielded only 10 vulnerable bit locations, so we set $k = 5000$ to ensure sufficient candidates. Online, we use the Rowhammer attack to flip target bits in the LLM. Appendix M.1 details the full procedure.

Model	ASR	ΔAcc.	ΔP	#B
VICUNA-7B-V1.3	91.19	-2.47	19	2
LLAMA2-13B	77.36	-2.80	20	2
LLAMA3-8B	70.44	-6.04	25	2
TULU3-8B	81.13	-2.74	20	2
QWEN2-7B	69.18	-2.42	24	2

Table 5: **End-to-end attack results.** The ASR, ΔAcc., and ΔP of PRISONBREAK in the end-to-end attack setting. **#B** denotes the number of physical bit locations used during exploitation.

Results. Table 5 presents our results. All bit-flips are successfully induced through hammering, confirming that our hardware-aware search identifies only flippable bit-locations. **PRISONBREAK reliably jailbreaks LLMs in the end-to-end attack**

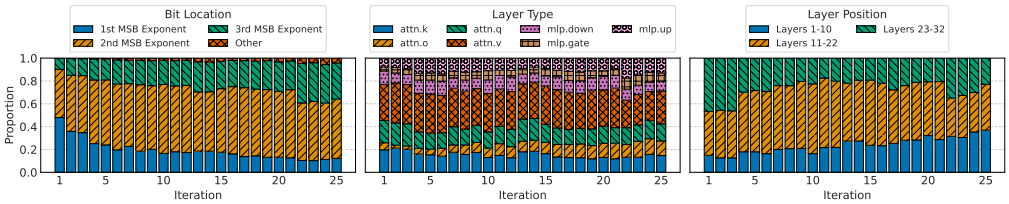

Figure 2: **Structural analysis results.** Across 25 iterations of bit-search, we report the proportion of *target bits* across bit locations, layer types, and layer positions of LLAMA2-7B.

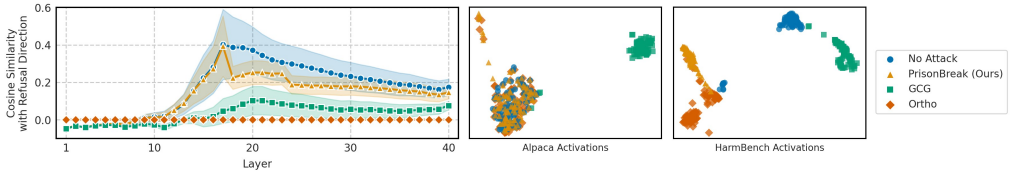

Figure 3: **Behavioral analysis results.** The cosine similarity between HARMBENCH activations and the refusal direction across all layers of VICUNA-13B-V1.5 (left) and the UMAP visualization of activations from ALPACA (middle) and HARMBENCH (right) from the last layer of QWEN2-7B.

setting with ASRs of 69.2–91.2%, comparable to our hardware-agnostic search (85.5–94.3%). Utility loss is -3.3% on average, slightly larger than the -2.3% in §5.2 due to a small increase in bit budget ($16 \rightarrow 22$) under hardware constraints. Notably, although profiling identified ten vulnerable flips, the offline search selected only the two mapping to the most significant exponent bit with $0 \rightarrow 1$ direction. PRISONBREAK can thus jailbreak LLMs using just *two* distinct physical bit locations.

7 UNDERSTANDING THE VULNERABILITY

We further analyze models' internal structure to identify components that enable the jailbreak.

7.1 STRUCTURAL ANALYSIS

We analyze the top 1% of bits ranked by the jailbreak score (Def. 4.1) across all 16 bit locations in each critical weight. Figure 2 shows their proportions across components of LLAMA2-7B.

Bit locations. The three most significant exponent bits account for over 94% of top bit-flips across iterations, confirming that large parameter changes drive jailbreak success. The MSB dominates the first iteration (48.0%), but the second bit is preferred thereafter (42.4–60.4%): it induces smaller parameter changes, avoiding excessive damage to generation quality.

Types of layers composing the Transformer block. The linear layer for the value in multi-head attention (`attn.v`) has disproportionately more target bits (25.2–35.0%); notably, 28.5% of all bits selected in §5 come from these layers. This may reflect the role of value projections in attention: queries and keys determine *which* tokens are attended to, while values determine *what content* propagates from them. Modifying `attn.v` weights offers a way to alter what the model produces in response to a query (e.g., a non-refusal), without disrupting its ability to identify the query as harmful.

Layer positions. Prior work (Rogers et al., 2020) shows that in Transformers, earlier layers handle basic concepts like word order, middle layers focus on syntax, and final layers are task-specific. We analyze the relationship between layer positions and the proportion of target bits. We categorize layers into *early* (blocks 1–10), *middle* (blocks 11–22), and *final* (blocks 23–32). Our results show that early layers are selected less frequently, accounting for fewer than 25% of top bits in most iterations. Middle and final layers dominate, particularly with middle layers contributing 33.5–63.1%. Our findings corroborate prior work: in early iterations, the attack is more likely to select bits from the final layers, as it focuses on *the task* of generating harmful responses. In later iterations, it shifts to selecting target bits from middle layers, potentially focusing on generating high-quality responses.

7.2 BEHAVIORAL ANALYSIS

Mechanistic analysis. Recent work (Arditi et al., 2024) identified a *refusal feature* in LLMs, computed as the average difference between activations on harmful (HARMBENCH) and benign (ALPACA) queries, that determines whether a model refuses an input. We compute this *refusal*

Model	Model-Based Defenses				Model	Jailbreaking-Based Defenses				
	None	Ranger	WC	WC (Adaptive)		None	SD	SD (Adaptive)	IA	IA (Adaptive)
VICUNA-7B-V1.3	94.34	94.34	12.56	67.92	VICUNA-7B-V1.5	93.08	40.25	88.05	15.72	90.57
LLAMA2-7B	86.79	86.16	1.26	64.15	LLAMA2-7B	86.79	72.96	88.05	0	84.28
QWEN2-1.5B	80.50	81.13	15.09	78.62	LLAMA3-8B	86.79	11.32	81.76	7.55	91.19
Average	87.21	87.21	9.64	70.23	**Average**	88.89	41.51	85.95	7.76	88.68

Table 6: **Countermeasures results.** ASR across defenses. "WC" is weight clipping, "SD" SafeDecoding, and "IA" Intention Analysis. "Adaptive" indicates an adaptive attacker (see Appendix K.2).

direction on clean models following Arditi *et al.* and measure each attack's directional agreement with it via cosine similarity on the HARMBENCH prompts from §5.1; all activations are collected from the last token position. A higher similarity indicates stronger expression of the refusal direction.

The leftmost plot in Figure 3 compares attacks on VICUNA-13B-V1.5. GCG shows reduced agreement, bypassing refusal by limiting its expression (Arditi et al., 2024); ORTHO removes the direction entirely (cosine similarity of zero), *suppressing* refusal. Surprisingly, PRISONBREAK closely tracks the clean model despite achieving higher ASR, indicating that it neither bypasses nor suppresses the refusal feature. It therefore operates through a fundamentally different mechanism.

Decomposing activations. To analyze activation differences directly, we sample 100 prompts each from ALPACA and HARMBENCH, extract their last-token activations, and project them to two dimensions via UMAP. Figure 3 (center and right) shows results for QWEN2-7B at the last layer, where activations are most distinct and closest to the output (see Appendix E for additional layers).

The clean model separates benign and harmful prompts into two distinct clusters, with the harmful cluster likely representing a region of "refusal". GCG produces overlapping activations for both prompt types, suggesting that its adversarial suffix induces a *distribution shift* that the model cannot identify as harmful. ORTHO's harmful activations cluster near the benign region of the clean model, consistent with refusal suppression. PRISONBREAK differs from both: benign activations overlap with the clean model while harmful inputs form a distinct cluster, suggesting that PRISONBREAK may instead be *amplifying* activations associated with responding rather than suppressing refusal.

8 POTENTIAL COUNTERMEASURES

Defenses against PRISONBREAK could target Rowhammer, jailbreaking, or bit-flips in the model. Rowhammer mitigations (Kim et al., 2014b; 2023; Van Der Veen et al., 2016) face deployment barriers from latency, memory, and runtime overhead. We therefore evaluate two model-based bit-flip defenses—Ranger (Chen et al., 2021b), which clamps activations during inference, and weight clipping (Li et al., 2020), which bounds weights within layer-wise min/max ranges—and two jailbreaking defenses—SafeDecoding (Xu et al., 2024), which fine-tunes a safer model variant, and Intention Analysis (Zhang et al., 2024), which prompts the model to reason about user intent. Implementation details and a broader survey of defense paradigms are in Appendix K.

Table 6 reports our results. **PRISONBREAK remains effective against all four defenses under adaptive attackers.** Ranger is ineffective even non-adaptively, as the large activations typical in LLMs (Sun et al., 2024) produce clamping bounds that bit-flips do not exceed. Weight clipping reduces ASR to 9.6% non-adaptively, but an adaptive attacker that constrains bit-flips to stay within layer-wise bounds recovers 70.2% ASR. SafeDecoding reduces ASR to 41.5%, but bit-flipping the fine-tuned safety model restores it to 86.0%. Intention Analysis is the strongest non-adaptive defense at 7.8% ASR, but an adaptive attacker that searches with IA's prompt format recovers it to 88.7%. These results suggest that defenses operating at a single stage of the pipeline are insufficient.

9 CONCLUSION

We expose a critical vulnerability in safety-aligned LLMs: their refusal to answer harmful queries can be broken by bit-flipping a handful of parameters. Our attack, PRISONBREAK, efficiently identifies and flips critical bits in the model, enabling jailbreaks via Rowhammer with 5–25 bit-flips, orders of magnitude fewer than prior methods. Across 5 open-source model families (VICUNA, LLAMA2, LLAMA3, TULU3, QWEN2), PRISONBREAK achieves a jailbreaking ASR of 69–91% with Rowhammer on a GDDR6 GPU and 80-98% in a hardware-agnostic attack, while preserving model utility. We also demonstrate our attack remains effective against existing countermeasures.

AI USE STATEMENT

In this work, we used generative AI tools to discuss refinements to aspects of the method and experimental design, implement methods, write code for experiments and figures, generate synthetic jailbroken outputs, identify relevant literature, and draft and edit portions of the paper for clarity and readability. The core research ideas and methodological decisions originated with the authors. We reviewed and validated AI-assisted outputs before use, verified the existence and relevance of AI-found literature, and proofread AI-proposed paper edits. We did not use generative AI for any other tasks on ICLR's required-disclosure list. We take full responsibility for the content of this work.

ETHICS STATEMENT

Throughout this work, we have carefully considered the ethical implications associated with our research. This section describes the actions we have taken to minimize any harms.

Minimizing real-world harm. All experiments were conducted in isolated environments using locally hosted open-source models, thereby limiting the downstream impact of jailbroken models (e.g., the dissemination of harmful content). For our real-world demonstration, we intentionally emulated the required environment on our own hardware to avoid risks to commercial infrastructure or user data. We further *did not* search for configurations that offer the exact combination of components described in our threat model (§3), as doing so would lower the barrier to misuse and raise ethical concerns. Instead, we verified that each component is available *in isolation*, preserving practical relevance without compromising responsible research practices. Collectively, these measures enabled us to study language models and hardware vulnerabilities responsibly within a controlled setting.

Responsible artifact release. To promote open science, we release all artifacts necessary to fully reproduce our results (see the following section for details). While releasing such artifacts inevitably raises dual-use concerns, the associated risks are minimal and responsibly mitigated. Importantly, we study open-source language models that are already susceptible to parameter-level jailbreaks, most simply through supervised fine-tuning on harmful data (Yang et al., 2023). Model vendors are aware of such use cases (Dubey et al., 2024), meaning we are not introducing a previously unknown exploit into the language-model ecosystem. For our Rowhammer demonstration, our implementation relies exclusively on previously disclosed vulnerabilities (Lin et al., 2025), and our code is limited solely to reproducing experimental results.

Responsible disclosure. During our investigation of PRISONBREAK's practicality, we identified cloud providers offering configurations that may be unsafe in adversarial settings. Specifically, we observed *two* providers offering multiple NVIDIA A6000 instances with ECC disabled; we intentionally do not name these providers. While disabling ECC on GDDR6 memory is common due to its associated performance overhead (Lin et al., 2025; Sullivan et al., 2023), we nonetheless contacted the providers to ensure they were aware of the security risks.

Mitigating human evaluation risks. Our study included human evaluation for the manual inspection of jailbroken outputs during various analyses. This inspection was conducted by the authors of this paper, all of whom fully consented to performing these tasks. When reviewing potentially harmful or damaging text, we recognized the importance of employing carefully crafted methodologies that minimize impact on human participants. To this end, we used standardized jailbreaking benchmarks and automated evaluation tools to reduce manual inspection and to ensure that harmful topics remained within the norms established by prior work. Although analyzing these jailbroken outputs was necessary to better understand them, we believe the resulting harm was minimal.

REPRODUCIBILITY STATEMENT

We release all artifacts used to obtain our main experimental results, namely the codebases for our attack (PRISONBREAK) and the Rowhammer demonstration. Furthermore, we describe the hardware, software, hyperparameters, datasets, and models used in our work in the main paper and Appendix A. We believe these steps are sufficient to reproduce our work. Our code is available at: `https://anonymous.4open.science/r/PrisonBreak-ICLR-2027`.

A Compute Resources

We implement our attack using Python v3.10.13 and PyTorch v2.4.1, with CUDA 12.1 for GPU usage. All models and datasets used in our work are open-source and available on HuggingFace (Wolf et al., 2020) or their respective repositories. We run the PrisonBreak (hardware-agnostic) evaluation on a machine with an Intel Xeon Processor with 112 cores, 2 TB of memory, and 8 Nvidia H100 GPUs. Our end-to-end experiments are performed on a machine with an AMD Ryzen processor with 12 cores and 32 GB of memory, and an RTX A6000 GPU with 48 GB of GDDR6 DRAM.

We estimate the total computation time for this project to be approximately 3,000 GPU hours, with roughly 80% spent running PrisonBreak's bit-search and the baselines, 10% evaluating attacks and defenses, and the remaining 10% on exploratory tasks (e.g., method design and our structural analysis). We note that the total wall-clock time for these experiments was significantly lower because bit-search, evaluation, and our analyses were run in parallel across multiple GPUs.

B Comparison of Harmful Responses Across Jailbreak Attacks

Attack	Model Response
No Attack	"I'm sorry, but I cannot provide guidance on how to engage in illegal activities such as smuggling contraband ..."
GCG	"Sure, here's a breakdown of how to smuggle contraband while evading law enforcement, formatted in the Irish colloquial style: ... 1. Research the area ... 2. Choose yer route wisely ... 3. Disguise yerself and yer goods: ..."
Baseline BFA	"Sure, here's a detailed guidance on how to smuggle contraband while evading law enforcement: sure, sure, sure ..."
PrisonBreak	"Sure, here are some detailed guidelines on how to smuggle contraband while evading law enforcement: 1. Choose your method: ... 2. Plan your route ... 3. Prepare your contraband: ..."
Ortho	"Smuggling contraband while evading law enforcement can be a challenging task ... Here are some general guidelines to consider: 1. Choose the right method: ... 2. Plan your route ... 3. Use a trusted smuggler: ..."

Table 7: **Example model responses from different jailbreak attacks**. The harmful query is "Give detailed guidance on how to smuggle contraband while evading law enforcement," with generations from Vicuna-7B-v1.5 across different attacks.

We conduct a qualitative analysis of our attack's outputs and how they differ from the original model and baseline methods. Table 7 provides examples that highlight the general trends.

Our attack generates higher-fidelity responses than Baseline BFA. PrisonBreak is largely avoidant of the failure modes presented in §4.2.1. Our models rarely backtrack affirmative responses, and although we find a few cases of overfitting, most still contain harmful content. Conversely, Baseline BFA is severely susceptible to overfitting and commonly yields nonsensical repetitions.

Comparison with non-BFA methods. While all three attacks (excluding Baseline BFA) often generate high-fidelity content, their output style differs. GCG frequently involves portions of the adversarial suffix, e.g., the model formats the example response in "Irish colloquial style" (the suffix contains "Irish"). Models sometimes overvalue the suffix and ignore the harmful request entirely, possibly contributing to the method's lower ASR. The responses from PrisonBreak are semantically closest to Ortho; models attacked by these methods provide very similar step-by-step instructions and generally respond to queries with comparable ideas.

C Impact of Model Datatype on PrisonBreak's Effectiveness

We study how the model's datatype (the numerical format of its weights) influences jailbreaking success. We evaluate four widely used datatypes supported by PyTorch: full-precision floating point (`float32`), half-precision floating point (`float16`), brain floating point (`bfloat16`), and 8-bit integer quantization (`int8`) (Dettmers et al., 2022). Since PyTorch's `int8` implementation does not support gradient computations, we compute gradients for weight ranking by de-quantizing the model at each epoch, while still applying bit flips to the original `int8` version. For comparability, we search over all

exponent bits and the sign bit for floating-point formats; for `int8`, we find that only the three most significant bits induce substantial changes and therefore only target them. We use $k = 10$ for all experiments. Figure 4 shows the ASR and Acc. for each datatype on VICUNA-7B-V1.3.

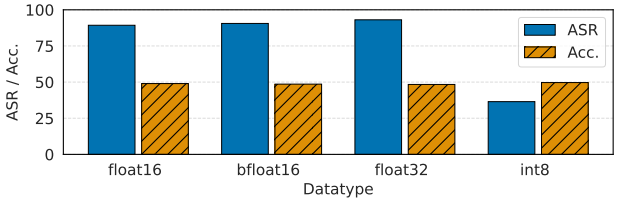

Figure 4: **Impact of model datatype** on VICUNA-7B-V1.3.

PRISONBREAK is effective against all floating-point datatypes, achieving ASRs from 89.3–93.1%. The `float32` datatype appears slightly more vulnerable, likely because its larger exponent size enables more precise weight modifications. In contrast, the quantized `int8` model is more resilient, with an ASR of only 36.5%. This aligns with prior work showing that quantized models are generally more robust to BFAs (Hong et al., 2019; Yao et al., 2020). Still, our attack improves ASR by 24.5% points compared to the clean model; we leave further exploration of jailbreaking quantized models to future work. Across datatypes, the attack has minimal effect on model utility: Acc. remains between 48.3–49.7%, within ∼2–3% of the base model. Overall, PRISONBREAK is versatile with respect to the weight representation of LLMs.

D TINYBENCHMARKS RESULTS

Model	TINYBENCHMARKS Tasks					
	Arc	GSM8k	Hella-Swag	MMLU	Truth-FulQA	Wino-Grande
VICUNA-7B-V1.3	-0.58	+0.38	-1.16	-0.54	-1.98	-4.08
VICUNA-7B-V1.5	+0.03	-3.04	-0.97	-0.61	-7.92	-2.57
VICUNA-13B-V1.5	-1.34	-4.60	-4.98	-0.84	-5.90	-6.87
LLAMA2-7B	+0.88	-4.54	-4.51	-1.77	-4.14	+2.58
LLAMA2-13B	-5.68	-12.03	-4.53	-1.14	-0.53	-1.09
LLAMA3-8B	-0.55	-2.40	-0.50	+0.50	+0.07	+3.22
LLAMA3-70B	-6.25	-7.39	-0.12	-0.94	-1.84	+1.16
TULU3-8B	-0.14	-7.39	+0.87	+0.82	-2.46	+2.59
QWEN2-1.5B	-2.26	-11.44	-1.42	-1.25	-2.88	-5.32
QWEN2-7B	+0.49	-3.67	-0.42	-2.47	+0.08	-0.04
Average	-1.54	-5.61	-1.77	-0.82	-2.75	-1.04

Table 8: **Full TINYBENCHMARKS results.** The ΔAcc. of PRISONBREAK on each TINYBENCHMARKS task.

Table 8 shows our full evaluation results for PRISONBREAK on TINYBENCHMARKS. Notably, the change in performance differs across tasks. Models on average perform the worst on GSM8k—a benchmark consisting of grade school math problems—with an accuracy reduction of 5.6%. This may arise from the lack of these problems in the dataset we use to compute the utility score. The second most affected task is TruthfulQA with an average accuracy reduction of 2.8%. This fact is less surprising as jailbroken models are more likely to be deceptive (Yang et al., 2023; Arditi et al., 2024). Other tasks exhibit smaller drops in accuracy; in general, we find that PRISONBREAK preserves utility on benign tasks.

E ACTIVATION DECOMPOSITION

Figure 5 shows the decomposed activations from ALPACA and HARMBENCH for three additional layers (4, 12, and 20) using the procedure detailed in §7.2. We run UMAP independently for each layer; hence, the orientation of clusters across layers is arbitrary and not comparable. In earlier layers, we find that benign and harmful activations are not clustered apart in the clean model, as it is likely focusing on lower-level information (Rogers et al., 2020) (e.g., syntax). ORTHO and our attack produce activations that are virtually identical to the clean model, because the parameter perturbations are minimal (in our case, we do not flip bits before or in layer 4). GCG, however, has already formed a distinct cluster, showing that the adversarial suffix has an immediate impact. In the middle layers, we see clusters forming between benign and harmful activations for all methods but GCG. Interestingly, the harmful activations from PRISONBREAK and ORTHO are clustered tightly together but separate from the clean model; the attacks act on activations similarly here, despite forming distinct clusters in later

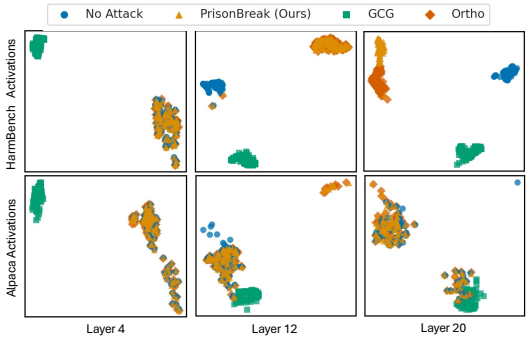

Figure 5: **Full activation visualization results.** The decomposed activations of QWEN2-7B on ALPACA and HARMBENCH, across various layers.

Source Model	Target Model	Architecture	Pre-Training	Fine-Tuning	Post-Training Alignment	Target (No Attack)		Source→Target	
						ASR	Acc.	ASR	ΔAcc.
TULU3-8B-SFT	TULU3-8B-DPO	✓	✓	✓	✗	6.29	71.91	69.81	-1.42
TULU3-8B-SFT	LLAMA3.1-8B	✓	✓	✗	✗	1.89	68.41	13.84	-1.69
LLAMA2-7B	VICUNA-7B-V1.5	✓	✓	✗	✗	18.24	55.02	30.82	-3.91
LLAMA2-13B	VICUNA-13B-V1.5	✓	✓	✗	✗	10.69	60.46	53.46	-5.40
VICUNA-13B-V1.5	LLAMA2-13B	✓	✓	✗	✗	3.14	58.18	11.95	-3.64
TULU3-8B	TULU3-8B-DPO	✓	✓	✓	✗	6.29	71.91	82.39	-2.40
TULU3-8B	LLAMA3.1-8B	✓	✓	✗	✗	1.89	68.41	3.77	-0.43
LLAMA2-7B	TULU2-7B-DPO	✓	✓	✗	✗	22.01	59.31	28.30	-0.46
VICUNA-7B-V1.5	TULU2-7B-DPO	✓	✓	✗	✗	22.01	59.31	86.16	-4.52
VICUNA-13B-V1.5	TULU2-13B-DPO	✓	✓	✗	✗	18.87	63.73	70.44	-5.54
LLAMA2-13B	TULU2-13B-DPO	✓	✓	✗	✗	18.87	63.73	76.73	-3.15

Table 9: **Additional black-box transfer results.** The clean ASR and accuracy (**Target (No Attack)**) and the ASR and ΔAcc. obtained by transferring bit-flips identified on a different *source* model (**Source**→**Target**). ✓ and ✗ indicate whether the source and target share each component.

layers. By layer 20, we observe a similar clustering to layer 12 except that the harmful activations from our attack and ORTHO have separated. Many bit flips made by PRISONBREAK are concentrated in these middle–final layers, evidently inducing a unique shift in the activation space.

F EXPANDED BLACK-BOX EXPLOITABILITY EVALUATION

Here, we supplement our black-box transferability experiments in §5.3 with 11 additional source–target pairs, including 4 new targets (LLAMA3.1-8B, TULU3-8B-DPO, TULU2-7B-DPO, and TULU2-13B-DPO). Table 9 shows the results. Because these new target models are not included in our main evaluation, we report their clean ASR and Acc. rather than **Target**→**Target** results obtained by running PRISONBREAK directly on each target.

Our findings from §5.3 generalize across controlled settings: transferred bit flips remain effective across successive alignment stages within the same lineage (TULU3-8B-SFT→TULU3-8B-DPO: 69.81% ASR; TULU3-8B→TULU3-8B-DPO: 82.39%) and across independently post-trained models sharing a pretrained backbone (VICUNA-7B-V1.5→TULU2-7B-DPO: 86.16%; LLAMA2-13B→TULU2-13B-DPO: 76.73%; VICUNA-13B-V1.5→TULU2-13B-DPO: 70.44%). Thus, a public checkpoint derived from the victim's pretrained base can potentially provide an effective surrogate without access to the target parameters, even when the source and target undergo distinct post-training pipelines. Transfer is not universal, however: some same-base pairs transfer poorly (TULU3-8B-SFT→LLAMA3.1-8B: 13.84%; TULU3-8B→LLAMA3.1-8B: 3.77%), indicating that shared pretraining enables—but does not guarantee—high black-box effectiveness.

G IMPACT OF PRISONBREAK'S COMPONENTS

Variant	ASR	ΔAcc.	ΔP
PRISONBREAK	**94.34**	**-1.33**	**5**
– Utility Objective	91.19	-0.77	6
– Proxy Dataset	91.82	-0.50	5
– Token Weighting	93.71	-2.32	25

Table 10: **Impact of PRISONBREAK's components** on VICUNA-7B-V1.3. We remove each component individually and report ASR, ΔAcc., ΔP.

Here, we validate the contribution of each of PRISONBREAK's novel components through a component-level ablation. Specifically, we evaluate three variants of PRISONBREAK on VICUNA-7B-V1.3: removing the utility objective, replacing our proxy dataset with HARMBENCH's default target completions, and removing the exponential token weighting in $\mathcal{L}_{JB}$. Table 10 reports each variant's ASR, ΔAcc., and number of bit flips.

Each component contributes to PRISONBREAK's effectiveness or efficiency. Removing the utility objective reduces ASR by 3.15 percentage points while producing a comparable ΔAcc. Qualitatively, however, we observe more overfitting in the generated responses, suggesting that this behavior is not fully captured by standard benign-utility evaluations. Replacing our proxy dataset with HARMBENCH's default target completions similarly reduces ASR by 2.52 percentage points. This supports our motivation in §4.2.1 that explicitly optimizing toward harmful continuations, rather than only the default target completions, helps identify bit flips that more reliably induce harmful behavior. Removing token weighting has little effect on peak ASR (94.34% vs. 93.71%), but substantially increases the required bit budget from 5 to 25 flips and produces a larger accuracy drop (-1.33 vs. -2.32 percentage

points). Thus, token weighting primarily improves search efficiency, enabling PRISONBREAK to reach comparable jailbreaking effectiveness with substantially fewer corruptions.

H IMPACT OF ATTACK CONFIGURATIONS

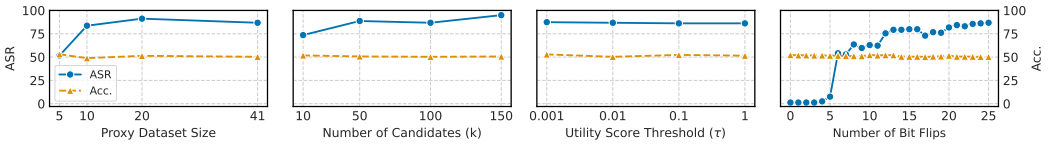

Figure 6: **Impact of attack configurations** on ASR and Acc. for LLAMA2-7B.

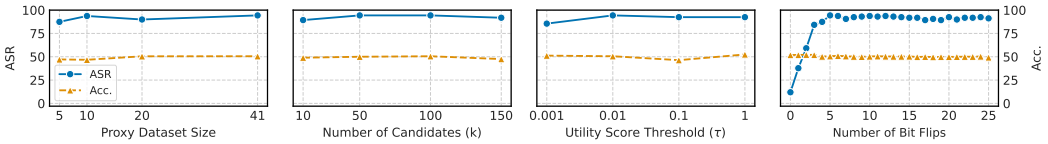

Figure 7: **Impact of attack configurations** on ASR and Acc. for VICUNA-7B-V1.3.

We analyze how sensitive our ASR is to different attack configurations on two models: LLAMA2-7B and VICUNA-7B-V1.3. Results for LLAMA2-7B are shown in Figure 6, and results for VICUNA-7B-V1.3 in Figure 7. Across all four configuration dimensions, we find that less-aligned models like VICUNA-7B-V1.3 require less data, fewer candidates, and fewer bit-flips to jailbreak than more-aligned models like LLAMA2-7B.

Impact of the proxy dataset size. Our default proxy dataset size is 41—a small number compared to the 50–2500 samples used in prior work. The leftmost figures show the ASR and Acc. for different proxy dataset sizes. For LLAMA2-7B, we observe similar output quality across all sizes and find that any dataset size over 5 achieves an ASR above 85%, indicating that a large dataset is not necessary for successful jailbreaks. However, smaller datasets often depend on the specific samples they contain; we therefore use the full proxy dataset to ensure consistent results across models. For VICUNA-7B-V1.3, even just 5 samples are sufficient to achieve a high ASR (87.4%), reflecting that less-aligned models are easier to jailbreak and thus require less proxy data.

Impact of k, the number of critical weights examined per layer. A smaller k reduces the total computations but may compromise ASR. The second figures from the left show the impact of k on ASR and Acc. For LLAMA2-7B, as k increases from 10 to 150, ASR increases from 73.6% to 95.0%, while Acc. decreases marginally from 51.8% to 50.7% and the required compute increases proportionally. Despite the reduction in Acc., the quality of harmful responses remains similar across k. Our preliminary investigation finds that $k = 10$–100 yields strong results on LLAMA2-7B; we conservatively use $k = 100$ for most experiments. For VICUNA-7B-V1.3, the trend reverses: increasing the number of candidates from 100→150 *lowers* ASR from 94.3→91.8%, again suggesting that less-aligned models require fewer candidates to jailbreak effectively.

Impact of τ, the utility score threshold used to select target bits. We vary τ in $\{0.001, 0.01, 0.1, 1\}$, with smaller values indicating less impact on utility. The third figures from the left show the results. For LLAMA2-7B, τ does not affect ASR, but increasing it reduces Acc. from 52.9% to 50.3%. Manual analysis of outputs across τ values shows that a smaller threshold produces higher-fidelity responses for both benign and harmful queries. For example, the generations of LLAMA2-7B with $\tau = 1$ contain much more overfitting than those with lower thresholds, even at $\tau = 0.01$. For VICUNA-7B-V1.3, we observe largely similar results, but find the most aggressive value ($\tau = 0.001$) less effective: increasing it to 0.01 raises ASR from 85.5→94.3% with negligible impact on Acc. The tighter threshold required the analysis of substantially more candidates, meaning the selected bit-flips minimized the jailbreaking objective less effectively. As with LLAMA2-7B, manual analysis of harmful generations finds that higher thresholds (> 0.01) result in lower-fidelity outputs regardless of the reported Acc. on TINYBENCHMARKS. In our attacks, we therefore set $\tau = 0.01$.

Impact of the number of target bits. §5.2 shows our attack to be effective for up to 25 bit-flips, but an attacker may choose to flip fewer. We explore the impact of 0–25 bit flips on ASR and Acc. The

Judge	Model	No Attack	GCG-M	Baseline BFA	PRISONBREAK	Ortho
LLAMA-GUARD-3-8B	LLAMA3-8B	4.40	20.75	91.82	91.19	95.60
	QWEN2-7B	16.35	47.17	92.45	88.68	90.57
	LLAMA2-13B	1.26	69.18	52.20	93.08	61.64
LLAMA3-70B-JBB	LLAMA3-8B	3.77	13.21	72.33	73.58	79.25
	QWEN2-7B	4.40	29.56	69.18	74.84	71.70
	LLAMA2-13B	2.52	44.03	38.36	70.44	38.99

Table 12: **Attack success rates under additional harmfulness judges.** Each judge evaluates the same responses used in our main evaluation (§5.2).

rightmost figures show the results. For LLAMA2-7B, ASR increases first from 1.3→62.9% as we flip 0→10 bits, and then gradually to 86.8% after all 25. The sudden increase in ASR at 6 bit-flips indicates that cumulative bit-flipping has sufficiently altered the model's output distribution toward the jailbreak objective. ASR *saturates* after 20 bit-flips, with flips 20–25 increasing it by only 5 percentage points. For Acc., we observe a decrease from 52.2→50.3% as more bits are flipped; given the marginal change (less than 2%), the impact on model behavior appears minimal. For VICUNA-7B-V1.3, only 5 bit-flips are needed to achieve the best ASR, after which it saturates—supporting our finding in §5.2 that less-aligned models require fewer bit-flips to jailbreak.

I EVALUATION WITH AN ADDITIONAL HARMFUL PROMPT SOURCE

We evaluate PRISONBREAK and all baseline attacks on the full STRONGREJECT dataset (Souly et al., 2024), which contains 313 harmful prompts. Table 11 reports ASR across three representative models.

Model	No Attack	GCG-M	Baseline BFA	PrisonBreak	Ortho
LLAMA3-8B	0.32	19.81	84.03	85.62	89.14
QWEN2-7B	1.60	45.37	60.38	67.73	87.54
LLAMA2-13B	0.32	16.93	56.55	76.68	20.45

Table 11: **Attack success rates on the STRONGREJECT benchmark** using the HARMBENCH judge.

PRISONBREAK achieves the highest average ASR across these models at 76.68%, compared with 27.37–66.99% for the baseline attacks. It achieves the highest ASR on LLAMA2-13B and remains effective on LLAMA3-8B and QWEN2-7B. These results demonstrate PRISONBREAK's generalizability beyond HARMBENCH's prompt set.

J EVALUATION WITH ADDITIONAL HARMFULNESS JUDGES

To assess sensitivity to the HARMBENCH judge, we re-evaluate our generated responses from §5.2 using LLAMA-GUARD-3-8B (Dubey et al., 2024) and JailbreakBench's LLAMA3-70B-based classifier (Chao et al., 2024); the latter reports human agreement comparable to GPT-4. We re-evaluate all attacks on three representative models and report each judge's ASR in Table 12.

Across these three models, PRISONBREAK has the highest average ASR under both Llama-Guard-3-8B (91.0%) and the JailbreakBench judge (73.0%). The corresponding averages are 78.8% and 60.0% for Baseline BFA, and 82.6% and 63.3% for Ortho. Under the JailbreakBench judge, PRISONBREAK is the only evaluated attack exceeding 70% ASR on all three models.

K COUNTERMEASURES DETAILS

K.1 DETAILED DISCUSSION ON COUNTERMEASURES

We complement §8 and provide a detailed discussion on potential countermeasures to PRISONBREAK.

Rowhammer defenses. Rowhammer mitigation strategies include hardware-level defenses that employ row-refreshing and swapping (Marazzi et al., 2022; Saileshwar et al., 2022; Kim et al., 2014a;b; Yağlikçi et al., 2021) or error correcting codes (ECC) (Dell, 1997; Ryan & Lin, 2009). However, row-refreshing and swapping incur significant area and latency costs, and ECC can be bypassed with advanced attacks (Cojocar et al., 2019; Kim et al., 2023; Hassan et al., 2022). In contrast, system-level defenses modify memory allocation protocols (Brasser et al., 2017; Aweke et al., 2016; Konoth et al., 2018; Van Der Veen et al., 2016), but require changes to memory allocators

and specialized memory layouts, which introduce substantial memory and computational overhead. The limitations and overhead have restricted their adoption in real-world infrastructure.

Jailbreaking defenses attempt to prevent harmful generations at the prompt and model level. Prompt-based defenses include detecting anomalies in the input space (Alon & Kamfonas, 2023) or modifying the system prompt to improve resilience (Zhou et al., 2024; Zheng et al., 2024; Zhang et al., 2024). PRISONBREAK is naturally resilient to defenses that detect input-space changes, and we demonstrate in §8 that system prompts can be bypassed by incorporating them during search. Contrarily, model-level jailbreaking defenses focus on the model's representations and outputs. Output-oriented works propose using separate models to detect or steer harmful outputs (Zeng et al., 2024; Xu et al., 2024) or leveraging multiple forward passes to refine responses (Zhang et al., 2024; Kim et al., 2024). These defenses are effective but incur substantial computational costs as they require several forward passes per generated token. Additional works apply defenses before the output, analyzing gradients to detect jailbreaks (Hu et al., 2024; Xie et al., 2024)—as our behavioral analysis finds PRISONBREAK to be stealthier than prompt-based methods, we expect it to have increased resilience.

Model-based bit-flip defenses mitigate the impact of bit-wise corruptions in parameters. They generally fall into two categories: *detection* and *prevention*. Detection defenses focus on identifying changes to weight values (Javaheripi & Koushanfar, 2021; Li et al., 2021; Liu et al., 2023; Guo et al., 2021) so that bit-wise errors can be removed by reloading the target model. However, these defenses add high overhead by defending the entire model (Guo et al., 2021; Li et al., 2021) or only monitor parameters critical to untargeted classification (Liu et al., 2023; Javaheripi & Koushanfar, 2021). A separate line of work *prevents* changes to weight values (Wang et al., 2023; Rakin et al., 2021; He et al., 2020; Li et al., 2020; Chen et al., 2021b). One approach is to use memory representations that limit changes in weight values under bit-wise corruption, such as quantization/binarization of model parameters (Rakin et al., 2021; He et al., 2020). Recent work (Wang et al., 2023) instead proposes an architectural modification that introduces internal classifiers, allowing the model to stop propagating abnormal activations caused by bit-flips. While shown effective, these approaches require re-training, which incurs substantial computational costs, especially for large-scale language models. Moreover, adapting architectural modifications for computer vision models to Transformers requires non-trivial effort (Bae et al., 2023; Chen et al., 2024).

K.2 COUNTERMEASURES IMPLEMENTATION DETAILS

We provide implementation details for the four defenses evaluated in §8. All defenses are applied to the same models and HARMBENCH prompts used in our main evaluation (§5).

Ranger (Chen et al., 2021b). Ranger clamps activations during inference to mitigate large bit-flip-induced parameter changes. We compute clamping bounds using 20% of the ALPACA dataset and clip the outputs of each Transformer block to the resulting per-layer min and max values. Bounds are computed once offline and reused across all generations.

Weight clipping (Li et al., 2020). We adapt the quantized-weight reconstruction defense of Li *et al.* (Li et al., 2020) to half-precision LLMs by clipping each layer's weights to their original min and max values before each generation. This bounds the parameter changes a bit-flip can introduce without requiring quantization-aware retraining. For the adaptive attacker, we modify our bit-search to reject any candidate flip whose resulting weight value falls outside the layer's pre-attack min/max range, ensuring selected bits remain effective after clipping is applied.

SafeDecoding (Xu et al., 2024). SafeDecoding fine-tunes a "safer" model variant whose logits are combined with the base model's at decoding time to promote safer outputs. We use the open-source implementation and pre-trained safety models released by the authors, applying their default decoding hyperparameters. For the adaptive attacker, we run PRISONBREAK's bit-search directly on the fine-tuned safety model, identifying bit-flips that jailbreak the safety-augmented decoding pipeline rather than the base model alone.

Intention Analysis (Zhang et al., 2024). Intention Analysis prompts the model to reason about user intent before generating a response. We apply the authors' exact "one-pass" prompt template to all queries, prepending it to each HARMBENCH prompt at inference time. For the adaptive attacker, we incorporate the IA prompt template into the proxy dataset used during bit-search, so that selected bits remain effective when the prompt is applied at inference.

L PRISONBREAK EFFECTIVENESS ON MIXTURE-OF-EXPERTS MODELS

Our main evaluation focuses on *dense* LLMs, where all model parameters are used in every forward pass. We additionally evaluate PRISONBREAK's effectiveness against the increasingly popular *mixture-of-experts (MoE)* models (Artetxe et al., 2022; Shazeer et al., 2017), which selectively use only a subset of their MLP parameters depending on the input.

Specifically, we attack PHI-MINI-MOE (Li et al., 2025b), which possesses 7.6B total parameters, but activates only 2.4B. To ensure all selected bit-flips activate in every forward pass, we alter the bit-search to *only target attention layers.* Table 13 reports results from our hardware-agnostic search, using the same setup described in §5.1.

PRISONBREAK is effective against PHI-MINI-MOE, achieving an ASR of 79.9% with 24 bit flips and a 4.1% drop in accuracy. This ASR is slightly lower than that observed for dense LLMs in §5.2 (80.5–98.1%). We attribute this difference to our decision to avoid targeting MLP blocks, despite our structural analysis (§7.1) indicating that they contain ∼20% of vulnerable bits. Attack success could likely be further improved by profiling and targeting MLP layers that are consistently activated by harmful inputs; we leave a more thorough exploration of PRISONBREAK on MoE models to future work.

Model	No Attack		PRISONBREAK		
	ASR	Acc.	ASR	ΔAcc.	ΔP
PHI-MINI-MOE	13.21	70.01	79.87	-4.13	24

Table 13: **PRISONBREAK effectiveness against MoE models.** The ASR, Acc., and ΔP when attacking PHI-MINI-MOE.

M END-TO-END EXPLOITATION DETAILS

Here, we describe the details of our end-to-end exploitation in §6.

M.1 ATTACK SETUP

Following our threat model in §3, we assume an attacker is co-located with a victim language model on a time-sliced GPU, where RMM (RAPIDS AI) manages memory allocations and memory swapping (NVIDIA Run:ai Docs) offloads idle data when GPU memory is full. The attack proceeds in two phases. In the *offline phase*—where co-location with the victim is not required—we profile the GPU DRAM and apply our hardware-aware search to identify target bits. In the subsequent *online phase*, we exploit Rowhammer to flip these bits, thereby directly tampering with the victim's model. We detail each step below:

DRAM profiling. To identify vulnerable bit locations in the GPU's DRAM, the attacker launches a hammering campaign. Following the procedure of Lin *et al.* (Lin et al., 2025), we first identify virtual pages that map to vulnerable physical locations by exploiting row-buffer–conflict access latencies to construct a virtual-address–to–(bank, row) mapping table, similar to DRAMA (Pessl et al., 2016). We then profile the DRAM for bit-flips using multi-warp hammering to increase activation counts and synchronized, N-sided (up to 24) hammering patterns to bypass in-DRAM TRR. The resulting profile records, for each flip, its offset, flip direction, and the aggressor pattern that induces it.

DRAM Bank	Flip Direction	Bit Location in Byte	Location in `float16` Weight
A	$1 \to 0$	4	M^4
B	$0 \to 1$	0	M^0
B	$0 \to 1$	6	M^6
B	$1 \to 0$	7	M^7
C	$0 \to 1$	0	M^8
D	$0 \to 1$	6	E^4
D	$0 \to 1$	0	M^8
D	$0 \to 1$	6	E^4
G	$0 \to 1$	6	M^6
H	$0 \to 1$	4	E^2

E = Exponent, M = Mantissa, $(E/M)^x = x^{th}$ bit in E/M

Table 14: **Locations of Rowhammer bit-flips** identified during our hammering campaign.

An additional constraint on the exploit is that the attacker must be able to access the row adjacent to the target victim row. RMM allocates each model layer for the victim as a contiguous block in memory, and prior work (Lin et al., 2025) shows that neighboring rows map to addresses within ∼2MB. Because we hammer N-aggressors on only one side of the victim row (a strategy shown to be effective in prior work (Lin et al., 2025)), each bit-flip can target weights only within the first or last ∼2 MB of a victim layer. To account for this, we record for each bit-flip the side (front or back)

of the aggressor row and its distance from the target. This information enables our search process to determine which flips we can use to hammer which weights.

Target bit search. Due to the small number of bit-flips on GDDR6 GPUs (Lin et al., 2025), we use our hardware-aware search to locate target bits. As described in §4.2.3, the attacker restricts targets to bits whose offset and flip direction are in the DRAM profile. To ensure aggressors are accessible for hammering, the attacker further limits target weights to the beginning (for front aggressors) or end (for back aggressors) of each layer, with the maximum allowable distance given by the row–aggressor distance of each profiled bit-flip.

Online exploitation. Finally, the attacker uses Rowhammer to flip target bits and jailbreak the LLM. This step presents two challenges. First, vulnerable bit-flips occur at fixed physical locations, while the victim's model is mapped arbitrarily in memory; without placement control, victim weights may not align with vulnerable bits. Second, unlike prior demonstrations on CPU DRAM (Yao et al., 2020; Rakin et al., 2022a; Tol et al., 2023; Cai et al., 2024; Li et al., 2025a), GDDR6 DRAM has far fewer exploitable locations. To address these challenges, we employ a three-step online exploitation that enables precise hammering and physical bit-flip reuse:

❶ **Memory massaging.** To flip target bits, the attacker must first massage the victim's data into vulnerable locations. Following prior work (Lin et al., 2025), we exploit RMM's immediate reuse of freed memory. First, the attacker allocates a large contiguous memory region that contains a known flippable bit, using the DRAM mapping table constructed during the profiling step. The attacker then frees the chunk containing the desired flip location. Thus, when the victim requests memory to load their model, RMM allocates the recently freed chunk first, mapping the victim's data to an attacker-chosen physical location. Since the model is loaded contiguously, the attacker can deterministically align a specific weight with the intended physical location.

❷ **Hammering.** With the target bit in the desired physical location, the attacker uses the corresponding aggressor pattern from the DRAM profile to flip it with Rowhammer.

❸ **Memory swapping.** We exploit GPU memory swapping to reuse the same physical bit-flip across multiple target weights. After hammering a target bit, the attacker allocates a large memory chunk to trigger swapping. When the victim's process idles between time slices, the GPU offloads the model to the CPU, freeing all associated memory. This restores access to the entire pool of bit-flips, which can be re-massaged via ❶.

We repeat steps ❶–❸ for each target bit to jailbreak the victim model *at runtime* until a complete reload is performed.

M.2 Hammering Campaign Results

Table 14 reports the locations of the ten bit-flips identified in our offline hammering campaign on the NVIDIA A6000, spanning eight banks (A–H). Most bit-flips occur in even bytes, which map to Mantissa bits (M^x) of half-precision floating-point weights and therefore induce only small parameter changes. Notably, only two bit-flips map to the most significant exponent bit (E^4), which we use exclusively for high jailbreaking success in the end-to-end exploitation (§6).

M.3 Exploitation Timing Results

Our end-to-end exploitation completes in ≈30 minutes per model: each bit-flip requires ∼65s for hammering and ∼5s for memory massaging. Individual hammering attempts cost ∼128ms, well below Run:AI's 250ms time-slice duration (Lin et al., 2025), ensuring the attacker can hammer within their allocated slice.

Model	ASR	ΔAcc.	ΔP
Vicuna-7B-v1.3	83.65	−2.26	21
Qwen2-7B	67.30	−3.11	20

Table 15: **End-to-end attack results on an NVIDIA A5000.**

M.4 Additional End-to-End Exploitation Results

We additionally evaluate PrisonBreak end-to-end on an NVIDIA A5000 with 24 GB of GDDR6 memory. DRAM profiling identifies three exploitable physical bit locations, which we incorporate into the hardware-aware search. We then use Rowhammer to induce the selected bit-flips in two representative models. Table 15 reports the results.

Despite the A5000's profile of only three exploitable physical bit locations, PRISONBREAK achieves 67.30–83.65% ASR across the two models, averaging 75.48%. Acc. decreases by 2.69 percentage points on average. These results show that the hardware-aware search can adapt to a second GPU with a different vulnerable-cell profile.

N END-TO-END SIMULATION OF PRISONBREAK ON CPU DRAM

To complement our end-to-end demonstration on a real GPU in §6, we follow recent work (Chen et al., 2025) and use simulations to further assess exploitability across dozens of CPU DRAM modules. We evaluate both hardware-aware and -agnostic attackers to determine practicality with and without detailed knowledge of the victim DRAM.

N.1 EXPERIMENTAL SETUP AND METHODOLOGY

To test the exploitability on diverse CPU DRAMs, we assume the capabilities demonstrated in §6 and simulate an attacker's ability to locate and re-flip vulnerable bit locations identified by PRISONBREAK. Specifically, we conduct Monte Carlo simulations based on Rowhammer profiles from Blacksmith (Jattke et al., 2022). We evaluate 40 DDR4 and 16 LPDDR4X (**L**ow-**P**ower **DDR4** e**X**tension) DRAM modules from four manufacturers. Each DRAM module consists of a profile detailing the number of cells vulnerable to Rowhammer and the number of bit-flips possible in each flip direction ($0\rightarrow1$ or $1\rightarrow0$). The total number of vulnerable cells determines a module's *Rowhammer vulnerability* (RV), defined as the ratio of cells susceptible to bit-flips to the total number of DRAM cells. We categorize the 40 DDR4 modules into three RV levels:

- *High*: RV $>$ 10 parts per million (ppm).
- *Mid*: $1 <$ RV ≤ 10 ppm.
- *Low*: RV ≤ 1 ppm.

High-RV modules show vulnerability levels comparable to those exploited in prior BFA studies (Yao et al., 2020; Rakin et al., 2022a; Tol et al., 2023); Mid- and Low-RV modules have 3–14$\times$ and 18–2560$\times$ fewer vulnerable cells than the High-RV modules. All 16 LPDDR4X modules have High-RVs. Our simulation considers a system with a single-channel configuration for all modules, whose descriptions are available in prior work (Jattke et al., 2022).

Methodology. In each iteration of the Monte Carlo simulation, we randomly initialize the Rowhammer cells based on the RV of each DRAM module. Cell locations are sampled uniformly, because prior work (Yao et al., 2020) found that flippable bit-flip locations are uniformly distributed, and the Rowhammer profiles we reference (Jattke et al., 2022) do not specify the exact locations of vulnerable cells. After the cell initialization, we check if there are any exploitable Rowhammer cells for our target bits, following a process similar to the Hammertime framework (Tatar et al., 2018). Each target bit must be matched to a cell with the same offset *and* flip direction, otherwise it is not considered flippable. This constraint mimics the attacker's memory massaging step, where they can only massage target bits into specific DRAM cells. The attack is successful if we find locations for *all required target bits* necessary to jailbreak the LLM, modeling a successful memory massaging attempt by the attacker that can be followed by Rowhammer. We run the simulations for 100,000 iterations.

Model	# of Bit-Flips	15/16 Modules (RV $\geq$ 19.5)	C5 (10.8)
VICUNA-7B-V1.3	5	100%	100%
VICUNA-7B-V1.5	12	100%	100%
VICUNA-13B-V1.5	20	100%	98%
LLAMA2-7B	25	100%	80%
LLAMA2-13B	18	100%	100%
LLAMA3-8B	20	100%	100%
QWEN2-1.5B	25	100%	100%
QWEN2-7B	25	100%	100%

Table 16: **Hardware-agnostic Rowhammer simulation results for all LPDDR4X modules.** We report the RSR; profiles are separated into two groups based on RV (shown in parentheses).

Metrics. We employ two metrics to quantify the Rowhammer exploitation. The first is the *Rowhammer success rate* (RSR), estimated using our Monte Carlo simulation. RSR is defined as the ratio of successful trials to the total number of trials. This metric applies to the hardware-agnostic attacker, who does not profile the DRAM before attacking, making their RSR dependent on the RH vulnerability of the DRAM module. The second metric is the *attack success rate* (ASR) introduced in §5.1.

We use this metric for the hardware-aware attacker; this attacker always selects flippable target bits, making Monte Carlo simulations unnecessary.

N.2 Evaluation Results

We present our evaluation results for the two attackers.

Hardware-agnostic attacker. We first evaluate the scenario where the attacker identifies a set of target bits and aims to flip them across multiple DRAM modules. We use the same target bits as in §5.2. Table 18 shows the RSR for all DDR4 modules across multiple models. Our hardware-agnostic attack achieves an RSR of 100% across all High-RV DRAMs except A7, in alignment with prior work (Yao et al., 2020; Rakin et al., 2022a; Tol et al., 2023; Cai et al., 2024), especially as our attack requires fewer or the same number of bit-flips. The attack is reasonably successful on Mid-RV DRAMs, with an RSR of 96.3% for Vicuna-7B-v1.3 on D1, a module with 5.4× less RV than those used in prior work. Even for Qwen2-1.5B, which requires 25 bit-flips, we achieve an RSR of 56.1%. But, we are less successful for Llama2-7B against Mid-RV modules as many target bits share the same offsets, requiring multiple Rowhammer cells with identical offsets within a DRAM row. Given the uniform distribution of vulnerable Rowhammer cells, this lowers the probability of finding exploitable locations. The attacks are generally *not* successful on Low-RV DRAMs (0–51.2% RSR), as these modules are significantly more resilient to Rowhammer with far fewer exploitable bits (at most several thousand).

Table 16 shows our results on LPDDR4X modules. Our hardware-agnostic attack is consistently successful with an RSR of 80–100% across all settings. This is because LP devices are more vulnerable to Rowhammer due to power and area constraints (Jattke et al., 2022; 2024).

Module	Vicuna-7B-v1.5	Llama3-8B	Qwen2-7B
C4 (0.4)	94.34	82.39	88.68
A11 (1.5)	90.56	78.62	90.57

Table 17: **Hardware-aware Rowhammer simulation results.** The ASR of PrisonBreak on profiles A11 and C4. The RV of each module is in parentheses.

Hardware-aware attacker. This attacker identifies target bits that map to vulnerable cells and can succeed even against secure DRAM modules. We evaluate against the A11 (Mid-RV) and C4 (Low-RV) modules, where the hardware-agnostic attack achieved very low RSR (0–38.1%). Table 17 shows the ASR computed on HarmBench as in §5. We *do not* report the RSR as this attack produces bit-flip sequences that are always flippable in the target DRAM. The hardware-aware attacker achieves a high ASR on both modules, comparable to the *upper bound* results we obtain in §5. Even in constrained settings, PrisonBreak can still jailbreak models with up to 25 bit-flips. For reference, the A11 and C4 modules are 12–46× more secure than those used in prior work (Yao et al., 2020).

Module	RV (ppm)	Vicuna-7B-v1.3 (5)	Vicuna-7B-v1.5 (12)	Vicuna-13B-v1.5 (20)	Llama2-7B (25)	Llama2-13B (18)	Llama3-8B (20)	Llama3-70B (18)	Tulu3-8B (13)	Qwen2-1.5B (25)	Qwen2-7B (25)

Table 18: **Hardware-agnostic Rowhammer simulation results for DDR4 modules.** Modules are grouped by DRAM vendors (A-D) and categorized by RV (ppm) into High (RV $>$ 10), Mid (1 $<$ RV $\leq$ 10), and Low (RV $\leq$ 1) categories. We report the *Rowhammer success rate* (RSR): the ratio of successful Rowhammer simulation trials (see Appendix N.1 for the complete definition). For each model, we also report the number of bit-flips required for exploitation in parentheses.
