ABSTRACT

Efficiently learning solution operators for parametric partial differential equations (PDEs) is difficult when high-fidelity simulations are scarce and expensive, even though low-fidelity approximations are often abundant. We introduce Multi-Fidelity Physics-Informed Neural Processes (MF-PINP), an adaptive spectral framework for multi-fidelity PDE learning that models each fidelity as an auto-regressive correction to the preceding level while imposing governing equations at resolution-dependent tolerances. Learnable spectral position encodings equipped with sparsity-inducing log-uniform priors select frequencies suited to each resolution and capture multi-scale solution structure. Physics-informed cross-fidelity attention then fuses observations according to spatial proximity and PDE residuals, allowing the model to discount unreliable coarse information. We derive PAC-Bayes generalization bounds connecting spectral complexity to model capacity and calibration bounds for uncertainty propagated through the fidelity hierarchy. Experiments across benchmark parametric PDEs show that MF-PINP improves predictive accuracy, maintains well-calibrated uncertainty, and substantially reduces the need for expensive high-fidelity observations.

1 INTRODUCTION

Parametric partial differential equations (PDEs) are fundamental to computational science and engineering, governing phenomena from fluid dynamics Jameson et al. (1981) to electromagnetic simulations Taflove et al. (2005). Traditional numerical solvers require solving these systems from scratch for each parameter configuration, rendering real-time simulation prohibitively expensive. A critical challenge arises in the multi-fidelity landscape (as illustrated in Figure 1): high-fidelity simulations demand substantial computational resources (e.g., thousands of CPU-hours per automotive CFD simulation Slotnick et al. (2014)), limiting practitioners to dozens of expensive observations, while low-fidelity simulations using coarse grids Benner et al. (2015) can be produced abundantly but with compromised accuracy.

Deep learning has enabled data-driven surrogate models for PDEs. Physics-Informed Neural Networks (PINNs) Raissi et al. (2019) enforce PDE residuals via automatic differentiation, enabling mesh-free solutions without labeled data. Operator learning methods including DeepONet Lu et al. (2021) and Fourier Neural Operator Li et al. (2020a) learn mappings between function spaces, achieving generalization across PDE instances. Neural Processes Garnelo et al. (2018b) enable few-shot adaptation through meta-learning Vadeboncoeur et al. (2023). However, these methods assume abundant high-fidelity data. Classical multi-fidelity methods Kennedy & O'Hagan (2000); Perdikaris et al. (2017) model high-fidelity outputs as auto-regressive corrections $f_H(\mathbf{x}) = \varrho \cdot f_L(\mathbf{x}) + \delta(\mathbf{x})$ using Gaussian processes, providing principled uncertainty quantification but suffering from $\mathcal{O}(N^3)$ complexity. Recent neural approaches Lu et al. (2022); Meng & Karniadakis (2020) reduce computational cost but lack explicit hierarchical correction modeling and struggle with multi-scale features due to spectral bias Rahaman et al. (2019).

Existing approaches face three fundamental challenges. Current neural methods treat fidelity levels as separate data sources rather than explicitly modeling hierarchical correction relationships Kennedy & O'Hagan (2000); Le Gratiet & Garnier (2014), failing to leverage the inherent correlation structure between resolutions. Standard position encodings use predetermined frequency bases that cannot adapt to varying spectral content: low-fidelity data filters high-frequency components due to coarse

discretization, while high-fidelity observations resolve multi-scale structures Rahaman et al. (2019). Uniform physics-informed regularization across all fidelities is mismatched: coarse simulations satisfy governing equations only approximately due to discretization errors, while fine simulations can meet stringent conservation laws.

We introduce **Multi-Fidelity Physics-Informed Neural Processes (MF-PINP)**, an adaptive spectral neural process framework for multi-fidelity PDE learning that explicitly models auto-regressive corrections between fidelity levels with physics-based regularization. Our approach efficiently synthesizes abundant low-cost simulations with scarce high-fidelity measurements, producing calibrated uncertainties and achieving substantial computational speedups while requiring significantly fewer expensive samples. Our contributions are:

- A hierarchical neural process architecture with learnable spectral position encodings incorporating sparsity-inducing log-uniform priors for automatic frequency selection, enabling adaptive multi-scale representation across fidelity levels.
- A physics-informed cross-fidelity attention mechanism that adaptively fuses multi-resolution data based on spatial locality and PDE residual magnitudes, with hierarchical physics regularization enforcing governing equations at fidelity-appropriate tolerances.
- Theoretical analysis establishing PAC-Bayes generalization bounds for neural processes with spectral encodings and establishing uncertainty calibration bounds across fidelity hierarchies, validated through extensive experiments on benchmark parametric PDEs.

2 Related Work

Neural Processes and Meta-Learning for PDEs Neural Processes Garnelo et al. (2018a;b) provide a probabilistic meta-learning framework that conditions on context observations to predict at target locations, offering uncertainty quantification through variational inference. Extensions including Attentive Neural Processes Kim et al. (2019) employ attention mechanisms to compute context-dependent representations, while Convolutional Conditional Neural Processes Gordon et al. (2019) introduce translation equivariance for spatial data. Recent work has adapted Neural Processes to temporal dynamics Norcliffe et al. (2021) and incorporated physics constraints for parametric PDEs Vadeboncoeur et al. (2023). Bias-Spectrum Neural Processes (BSNP) combine architectural priors such as translation equivariance and locality with governing equations and boundary conditions, using stochastic collocation and mean-field physics enforcement to improve discretization robustness and uncertainty calibration Li et al. (2026). Transformer-based architectures such as TNP Nguyen & Grover (2023) and LBANP Feng et al. (2023) further improve expressiveness through self-attention over context sets with fixed sinusoidal positional encodings, enabling better handling of irregular observation patterns but using predetermined frequency bases that cannot adapt to varying spectral content across resolution levels. We note that SConvCNP Mohseni & Duffield (2024) also employs spectral representations in the NP family but focuses on stationary kernel approximation rather than multi-fidelity PDE solving.

Multi-Fidelity Modeling and Operator Learning Classical multi-fidelity methods model high-fidelity outputs as auto-regressive corrections $f_H(\mathbf{x}) = \varrho(\mathbf{x})f_L(\mathbf{x}) + \delta(\mathbf{x})$ Kennedy & O'Hagan (2000), extended through nonlinear auto-regressive GPs Perdikaris et al. (2017) and hierarchical Kriging Han & Görtz (2012). These Gaussian process approaches provide Bayesian uncertainty quantification but incur $\mathcal{O}(N^3)$ computational complexity. Neural operator methods including DeepONet Lu et al. (2021) and Fourier Neural Operator Li et al. (2020a) learn mappings between function spaces with improved scaling. Multi-fidelity extensions Lu et al. (2022); Meng & Karniadakis (2020) employ architectures such as separate encoders for each fidelity level with feature concatenation, or sequential transfer learning from low-fidelity to high-fidelity data. Graph neural operators Li et al. (2020b) and message-passing architectures Brandstetter et al. (2022) have also been explored for handling unstructured meshes across different discretizations.

Most closely related to our work, MFPC-Net Liu & Wang (2019) combines neural processes with physics-informed constraints for multi-fidelity surrogate modeling but uses fixed physics constraints without adaptive fidelity-dependent tolerances. MFRNP Niu et al. (2024) proposes a multi-fidelity residual neural process that explicitly models residuals between fidelity levels with a tailored ELBO

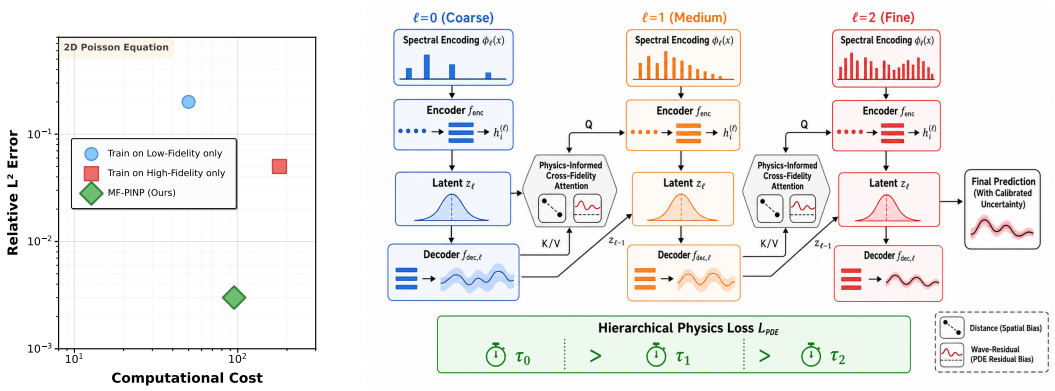

Figure 1: **MF-PINP for multi-fidelity PDE learning. (a)** Performance comparison between traditional methods (e.g., PINNs) trained on different fidelities and our MF-PINP approach on the 2D Poisson equation. **(b)** MF-PINP architecture.

and cross-fidelity information sharing, but lacks learnable spectral encodings for multi-scale representation. MF-HNP Wu et al. (2022) provides a unified framework for scalable multi-fidelity modeling in the neural process family but does not incorporate physics-informed attention with PDE residual weighting. Our work advances beyond these by jointly integrating all three components with theoretical guarantees, which none of the above methods achieve simultaneously.

Physics-Informed Neural Networks and Spectral Methods Physics-Informed Neural Networks Raissi et al. (2019) integrate governing equations into training by minimizing $\mathcal{L} = \mathcal{L}_{\text{data}} + \lambda\|\mathcal{N}[u] - f\|^2$, with recent developments including adaptive loss weighting Wang et al. (2021) and domain decomposition Jagtap et al. (2020). Neural networks exhibit spectral bias Rahaman et al. (2019), preferentially learning low-frequency components before high-frequency features. Fourier feature mappings Tancik et al. (2020) transform inputs using $\gamma(\mathbf{x}) = [\sin(2\pi\mathbf{B}\mathbf{x}), \cos(2\pi\mathbf{B}\mathbf{x})]$ with fixed matrix $\mathbf{B}$, while learnable spectral representations enable adaptive multi-scale modeling across varying problem characteristics. Random Fourier features Rahimi & Recht (2007) provide theoretical connections to kernel methods, and multi-scale neural networks Liu et al. (2020) employ parallel branches operating at different frequency bands. Hash-based multi-resolution encodings such as instant NGP Müller et al. (2022) achieve efficient spatial representations for 3D reconstruction, but their hash-collision design lacks the physically meaningful frequency selection required for PDE solution spaces.

Uncertainty Quantification in Deep Learning for PDEs Uncertainty quantification approaches include ensemble methods Lakshminarayanan et al. (2017), variational inference Yang et al. (2021), and deep kernel learning Wilson et al. (2016). Neural Processes provide uncertainty quantification through latent variable modeling $z \sim q(z|\mathcal{C})$, capturing epistemic uncertainty from limited observations. Calibration analysis Foong et al. (2020) examines whether predictive uncertainties accurately reflect prediction errors. Conformal prediction Angelopoulos & Bates (2021) offers distribution-free guarantees on coverage probabilities without parametric assumptions. Multi-fidelity Gaussian processes Perdikaris et al. (2017) propagate uncertainties hierarchically through Bayesian inference, while PAC-Bayes bounds relate empirical performance to population risk.

3 Methodology

We develop MF-PINP as an adaptive spectral neural process framework for multi-fidelity PDE learning, integrating learnable spectral position encodings, auto-regressive fidelity correction mechanisms, and physics-informed cross-attention, with the overall architecture illustrated in Figure 1. Our approach addresses three key challenges: discovering resolution-dependent spectral representations, propagating information across fidelity hierarchies, and enforcing governing equations with fidelity-adaptive tolerances.

Problem Formulation. Consider a parametric PDE governed by operator $\mathcal{N}$ over spatial domain $\Omega \subset \mathbb{R}^{d_x}$:

$$\mathcal{N}[u](\mathbf{x};\theta) = 0, \quad \mathbf{x} \in \Omega, \quad \theta \in \Theta, \tag{1}$$

where $u(\mathbf{x};\theta)$ is the solution field and θ represents physical parameters (e.g., diffusion coefficients, Reynolds numbers). Our framework operates as an *operator learner over parametric PDE families*: rather than solving a single PDE instance, it meta-learns to map context observations to predictions across the entire parameter space Θ. In multi-fidelity settings, we have access to L discretization levels indexed by $\ell \in \{0, 1, \ldots, L-1\}$, where $\ell = 0$ denotes the coarsest resolution and $\ell = L-1$ the finest. Each fidelity level provides context observations $\mathcal{C}_\ell = \{(\mathbf{x}_i^{(\ell)}, u_i^{(\ell)})\}_{i=1}^{N_\ell}$ sampled on grids of varying resolutions. At training time, the model observes N_0 abundant low-fidelity tasks (e.g., $N_0 = 500$ coarse simulations) and N_{L-1} scarce high-fidelity tasks (e.g., $N_{L-1} = 50$ fine simulations), each corresponding to a different parameter configuration θ. At test time, given a new unseen θ with limited context points, the model predicts the full solution field. Our goal is to learn a probabilistic model that predicts $p(u(\mathbf{x}^*;\theta)|\mathcal{C}_0, \ldots, \mathcal{C}_{L-1})$ at arbitrary query locations $\mathbf{x}^*$, leveraging complementary information across fidelities while quantifying prediction uncertainty.

3.1 Spectral Position Encoding with Adaptive Frequency Selection.

We introduce fidelity-adaptive spectral encodings that automatically discover resolution-dependent frequencies, addressing the limitation of fixed-frequency bases in existing NP extensions Nguyen & Grover (2023); Feng et al. (2023).

Definition 3.1 (Fidelity-Adaptive Spectral Encoding)**.** *For input $\mathbf{x} \in \mathbb{R}^{d_x}$ and fidelity level ℓ, the encoding $\phi_\ell : \mathbb{R}^{d_x} \to \mathbb{R}^{2Q}$ is:*

$$\phi_\ell(\mathbf{x}) = \sum_{q=1}^{Q} w_q \cdot \exp\left(-\frac{\|\mathbf{x}\|^2}{2\rho_q^2}\right) \cdot \begin{bmatrix}\cos(2\pi \boldsymbol{\mu}_q^\top \mathbf{x}) \\ \sin(2\pi \boldsymbol{\mu}_q^\top \mathbf{x})\end{bmatrix}, \tag{2}$$

where $\{w_q, \boldsymbol{\mu}_q, \rho_q\}_{q=1}^{Q}$ are learnable frequency weights, center frequencies, and spatial length scales (note: ρ_q here denotes length scales in the spectral encoding, distinct from the fidelity scaling parameters ρ_ℓ in the decoder).

Weights are parameterized as $w_q = \exp(\log \tilde{w}_q)$ under a truncated log-uniform prior $p(w_q) \propto 1/w_q$ on $[\epsilon, w_{\max}]$, inducing automatic relevance determination and enabling PAC-Bayes analysis (Theorem 4.1). A learnable cutoff $f_{\text{cutoff}}(\ell) = f_{\min} + \frac{\ell}{L-1}(f_{\max} - f_{\min})$ with smooth sigmoid masking enforces Nyquist-type resolution limits: low-fidelity encoders access only long-wavelength features, while high-fidelity encoders span the full spectral range. Context embeddings are formed as $\mathbf{h}_i^{(\ell)} = f_{\text{enc}}([\phi_\ell(\mathbf{x}_i^{(\ell)}), u_i^{(\ell)}, \theta, \mathbb{I}_\ell])$ via a residual MLP encoder.

3.2 Hierarchical Correction Neural Process Architecture.

Following the Kennedy-O'Hagan auto-regressive principle Kennedy & O'Hagan (2000), our architecture maintains separate latent distributions per fidelity level. At base fidelity $\ell = 0$, context embeddings are aggregated via mean pooling to parameterize the latent posterior:

$$q(\mathbf{z}_0|\mathcal{C}_0) = \mathcal{N}\left(g_{\mu_0}\left(\tfrac{1}{N_0}\sum_i \mathbf{h}_i^{(0)}\right),\, g_{\Sigma_0}\left(\tfrac{1}{N_0}\sum_i \mathbf{h}_i^{(0)}\right)\right), \tag{3}$$

with prior $p(\mathbf{z}_0) = \mathcal{N}(\mathbf{0}, \mathbf{I})$ Garnelo et al. (2018b). For $\ell > 0$, latent distributions are conditioned on both current contexts and lower-fidelity latents:

$$q(\mathbf{z}_\ell|\mathcal{C}_\ell, \mathbf{z}_{\ell-1}) = \mathcal{N}(g_{\mu_\ell}(\mathcal{C}_\ell, \mathbf{z}_{\ell-1}), g_{\Sigma_\ell}(\mathcal{C}_\ell, \mathbf{z}_{\ell-1})), \tag{4}$$

where $g_{\mu_\ell}, g_{\Sigma_\ell}$ are implemented via cross-fidelity attention (Section 3.3). Intuitively, $\mathbf{z}_{\ell-1}$ captures global PDE structure from abundant coarse data, while $\mathbf{z}_\ell$ refines this with high-resolution observations.

The decoder mirrors the auto-regressive correction principle. At base fidelity, predictions are generated directly:

$$\hat{u}_0(\mathbf{x}^*;\theta) = f_{\text{dec},0}([\phi_0(\mathbf{x}^*), \theta, \mathbf{z}_0]; \Theta_{\text{dec},0}), \tag{5}$$

where $f_{\text{dec},0}$ outputs mean $\mu_0(\mathbf{x}^*)$ and variance $\sigma_0^2(\mathbf{x}^*)$. For higher fidelities $\ell > 0$, predictions combine scaled lower-fidelity estimates with learned corrections:

$$\hat{u}_\ell(\mathbf{x}^*;\theta) = \rho_\ell \cdot \hat{u}_{\ell-1}(\mathbf{x}^*;\theta) + \underbrace{f_{\text{dec},\ell}([\phi_\ell(\mathbf{x}^*), \theta, \mathbf{z}_\ell])}_{\delta_\ell(\mathbf{x}^*)\text{: correction term}}, \tag{6}$$

where ρ_ℓ are learned scaling parameters initialized near unity, and δ_ℓ is deterministic given $\mathbf{z}_\ell$ (all stochasticity arises from $\mathbf{z}_\ell$). This decomposition enables hierarchical feature learning: base representations capture smooth global trends, while higher levels refine local structures and high-frequency details. The correction modules need only model residual discrepancies, simplifying learning at fine resolutions where data may be scarce.

Proposition 3.2 (Hierarchical Uncertainty Decomposition)**.** *Under the hierarchical auto-regressive decoder in Eq.* (6)*, the predictive variance at fidelity $\ell > 0$ decomposes as:*

$$\mathit{Var}[\hat{u}_\ell(\mathbf{x}^*)] = \rho_\ell^2 \cdot \mathit{Var}[\hat{u}_{\ell-1}(\mathbf{x}^*)] + \mathit{Var}[\delta_\ell(\mathbf{x}^*)] + 2\rho_\ell \cdot \mathit{Cov}[\hat{u}_{\ell-1}(\mathbf{x}^*), \delta_\ell(\mathbf{x}^*)] \tag{7}$$

When $\delta_\ell \perp \hat{u}_{\ell-1} \mid \mathbf{z}_\ell$, the covariance vanishes and uncertainty propagates additively across fidelity levels.

This decomposition shows that predictive uncertainty aggregates contributions across fidelity levels: base variance $\text{Var}[\hat{u}_0]$ captures global structural uncertainty, amplified by ρ_ℓ^2 and augmented by correction uncertainties $\text{Var}[\delta_\ell]$ at each refinement. The covariance term captures correlation between inherited structure and local refinements; under the conditional independence assumption (formalized in Theorem 4.2 below), it vanishes and total uncertainty decomposes cleanly.

Training maximizes the multi-fidelity ELBO:

$$\mathcal{L}_{\text{data}} = \sum_{\ell=0}^{L-1} \lambda_\ell \underbrace{\left[\mathbb{E}_{q(\mathbf{z}_\ell)} \log p(\mathcal{T}_\ell|\mathbf{z}_\ell, \mathcal{C}_\ell) - \beta\, \text{KL}(q(\mathbf{z}_\ell|\mathcal{C}_\ell)\|p(\mathbf{z}_\ell))\right]}_{\mathcal{L}_{\text{ELBO}}^{(\ell)}}, \tag{8}$$

where $\lambda_\ell \propto 1/N_\ell$ up-weights sparse high-fidelity observations.

3.3 Physics-Informed Cross-Fidelity Attention Mechanism.

Information fusion across fidelity levels requires careful consideration of spatial heterogeneity in data quality. Low-fidelity simulations may approximate smooth regions reasonably but fail near discontinuities, while sparse high-fidelity observations offer localized accuracy. Standard aggregation methods treat all locations equivalently, ignoring these quality variations. We introduce a physics-informed cross-attention mechanism that weighs contributions based on both spatial proximity and consistency with governing equations.

To fuse latent information from fidelity $\ell - 1$ (keys and values) with current level ℓ (queries), we employ multi-head attention. For context embeddings $\mathbf{h}_i^{(\ell)}$, we compute projections incorporating semantic features and spectral position encodings:

$$\mathbf{Q}_\ell = \mathbf{W}_Q[\mathbf{h}_i^{(\ell)}, \phi_\ell(\mathbf{x}_i^{(\ell)})], \quad \mathbf{K}_{\ell-1} = \mathbf{W}_K[\mathbf{h}_j^{(\ell-1)}, \phi_{\ell-1}(\mathbf{x}_j^{(\ell-1)})], \quad \mathbf{V}_{\ell-1} = \mathbf{W}_V \mathbf{h}_j^{(\ell-1)} \tag{9}$$

where $\mathbf{W}_Q \in \mathbb{R}^{d_k \times (d_h + d_\phi)}$, $\mathbf{W}_K, \mathbf{W}_V$ are learned projection matrices. The explicit inclusion of $\phi_\ell(\mathbf{x}_i^{(\ell)})$ in query/key projections, despite its presence in $\mathbf{h}_i^{(\ell)}$ via the encoder, serves as a relative positional bias analogous to rotary position embeddings Su et al. (2024), enabling the attention mechanism to directly reason about spatial relationships between cross-fidelity observations at different locations.

Standard scaled dot-product attention computes scores as $\mathbf{A}_{ij} = \text{softmax}(\mathbf{Q}_i^\top \mathbf{K}_j / \sqrt{d_k})$, reflecting semantic similarity but ignoring spatial structure and physics consistency. We augment attention scores with two physics-informed biases. First, spatial bias encourages local interactions:

$$s_{\text{spatial}}(\mathbf{x}_i, \mathbf{x}_j) = -\frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{\gamma^2}, \tag{10}$$

where γ is a learned length scale reflecting locality principles in PDEs. Second, physics residuals quantify lower-fidelity reliability:

$$r_{\text{PDE}}(\mathbf{x}_j^{(\ell-1)}) = \left\| \mathcal{N}[\hat{u}_{\ell-1}](\mathbf{x}_j^{(\ell-1)}; \theta) \right\|, \tag{11}$$

measuring how well lower-fidelity predictions satisfy governing equations. High residuals indicate unreliable approximations (e.g., near under-resolved shocks) and receive reduced weight.

Combining these components yields augmented attention scores:

$$\tilde{\mathbf{A}}_{ij} = \text{softmax}\Big(\frac{\mathbf{Q}_i^\top \mathbf{K}_j}{\sqrt{d_k}} + \alpha \cdot s_{\text{spatial}}(\mathbf{x}_i, \mathbf{x}_j) - \beta \cdot r_{\text{PDE}}(\mathbf{x}_j) \Big) \tag{12}$$

where α, β are learned scalars. In smooth regions with low residuals, the model relies on inherited structure; near discontinuities with high residuals, it focuses on current-level observations.

To further control information flow, we introduce residual-gated fusion. Cross-attention outputs are blended with self-aggregated representations $\mathbf{z}_\ell^{\text{self}}$ using learned gates:

$$\mathbf{z}_\ell = \sigma(g_\ell) \odot \mathbf{z}_\ell^{\text{self}} + (1 - \sigma(g_\ell)) \odot \text{Attn}(\mathbf{Q}_\ell, \mathbf{K}_{\ell-1}, \mathbf{V}_{\ell-1}), \tag{13}$$

where $g_\ell = h_{\text{gate}}([\mathbf{z}_\ell^{\text{self}}, \bar{r}_{\text{PDE}}^{(\ell-1)}])$ and $\bar{r}_{\text{PDE}}^{(\ell-1)}$ is the average lower-fidelity PDE residual. When $\bar{r}_{\text{PDE}}^{(\ell-1)}$ is small, gates favor cross-fidelity information; when large, gates prioritize current-level observations.

3.4 Multi-Fidelity Physics-Informed Training Objective.

We incorporate governing equations as soft constraints with fidelity-adaptive tolerances. The PDE residual loss at level ℓ is:

$$\mathcal{L}_{\text{PDE}}^{(\ell)} = \frac{1}{|\mathcal{X}_{\text{col}}^{(\ell)}|} \sum_{\mathbf{x} \in \mathcal{X}_{\text{col}}^{(\ell)}} \|\mathcal{N}[\hat{u}_\ell](\mathbf{x}; \theta)\|^2, \tag{14}$$

aggregated with decreasing tolerance weights $\tau_\ell = \tau_0 \cdot 2^{-\ell}$ (stricter at finer resolutions). Boundary and initial conditions are enforced only at the finest fidelity to avoid conflicts with coarse-grid inaccuracies:

$$\mathcal{L}_{\text{BC}} = \frac{1}{|\mathcal{X}_{\text{BC}}|} \sum_{\mathbf{x} \in \mathcal{X}_{\text{BC}}} \|\hat{u}_{L-1}(\mathbf{x}) - g(\mathbf{x})\|^2, \quad \mathcal{L}_{\text{IC}} = \frac{1}{|\mathcal{X}_{\text{IC}}|} \sum_{\mathbf{x} \in \mathcal{X}_{\text{IC}}} \|\hat{u}_{L-1}(\mathbf{x}, 0) - u_0(\mathbf{x})\|^2. \tag{15}$$

The complete objective is:

$$\mathcal{L}_{\text{total}} = \underbrace{\sum_{\ell=0}^{L-1} \lambda_\ell \mathcal{L}_{\text{ELBO}}^{(\ell)}}_{\text{Data Fidelity}} + \underbrace{\lambda_{\text{PDE}} \sum_{\ell} \tau_\ell \mathcal{L}_{\text{PDE}}^{(\ell)}}_{\text{Physics}} + \underbrace{\lambda_{\text{BC}} \mathcal{L}_{\text{BC}} + \lambda_{\text{IC}} \mathcal{L}_{\text{IC}}}_{\text{Constraints}}. \tag{16}$$

Training uses a two-stage strategy: first, we optimize only data terms $\mathcal{L}_{\text{ELBO}}^{(\ell)}$ to learn robust base representations; second, we gradually anneal in physics losses using cosine scheduling $\lambda_{\text{PDE}}(t) = \lambda_{\text{PDE}}^{\max} \cdot (1 - \cos(\pi t / T_{\text{anneal}}))/2$, preventing physics constraints from overwhelming data likelihood early in training. For computational efficiency, collocation points are sampled proportional to $r_{\text{PDE}}(\mathbf{x})^2$ Wu et al. (2023), concentrating evaluations where the model violates physics constraints (full details in Appendix A.3).

4 Theoretical Analysis

We provide generalization guarantees for our framework and establish conditions under which hierarchical multi-fidelity predictions yield approximately calibrated uncertainties. Our analysis reveals how spectral encodings with log-uniform priors control model complexity, and demonstrates that auto-regressive correction mechanisms propagate uncertainties consistently across fidelity levels. Detailed proofs are in Appendix B.

Theorem 4.1 (Generalization Bound for Spectral Neural Processes)**.** *Let $\mathcal{H}_{spec}$ be the hypothesis class of neural processes with Q-component spectral encodings and latent dimension d_z. For a distribution $\mathcal{D}$ over parametric PDE tasks and n sampled tasks, with probability at least $1-\delta$:*

$$\mathbb{E}_{\tau\sim\mathcal{D}}[\mathcal{L}(\hat{f}_\tau)] \le \frac{1}{n}\sum_{i=1}^{n}\mathcal{L}(\hat{f}_{\tau_i}) + \sqrt{\frac{2KL(q_{freq}\|p_{freq})}{n}} + \mathcal{O}\left(\sqrt{\frac{d_z\log n}{n}}\right) + \epsilon_{trunc}(Q) \tag{17}$$

where q_{freq} is the learned frequency distribution, p_{freq} is the truncated log-uniform prior, and $\epsilon_{trunc}(Q) = \mathcal{O}(Q^{-1/2})$.

Smaller $\mathrm{KL}(q_{\text{freq}}\|p_{\text{freq}})$ improves generalization by learning fewer active frequencies. The truncated log-uniform prior induces sparsity through heavy penalties on small frequency weights, performing automatic model selection. The truncation error $\epsilon_{\text{trunc}}(Q) = \mathcal{O}(Q^{-1/2})$ guides the choice of frequency budget Q, balancing approximation accuracy against model complexity.

Theorem 4.2 (Hierarchical Uncertainty Calibration)**.** *Consider the hierarchical decoder in Eq.* (6) *where $\delta_\ell(\mathbf{x}^*)$ is deterministic given $(\mathbf{x}^*, \theta, \mathbf{z}_\ell)$. Assume: (i) $\delta_\ell \perp \hat{u}_{\ell-1} \mid \mathbf{z}_\ell$; (ii) bounded third moments $\mathbb{E}[|\mathbf{h}^{(\ell)}|^3] \le M_3$. Then for confidence level $\alpha \in (0,1)$:*

$$\left|\mathbb{P}\big(u_{L-1}(\mathbf{x}^*) \in \big[\mu_{L-1} \pm z_{\alpha/2}\sigma_{L-1}\big]\big) - (1-\alpha)\right| \le \frac{C_{BE}\cdot M_3}{\sigma_{\min}^3\sqrt{N_{\min}}} + \epsilon_{var} \tag{18}$$

where $N_{\min} = \min_\ell N_\ell$, C_{BE} is the Berry-Esseen constant, and $\epsilon_{var} = \mathcal{O}(1/N_{\min})$.

Coverage converges to the nominal level at rate $\mathcal{O}(1/\sqrt{N_{\min}})$, so abundant low-fidelity observations improve calibration even when high-fidelity data is scarce. The auto-regressive structure correctly aggregates uncertainties: variance decomposes into inherited variance from lower fidelities (scaled by ρ_ℓ^2) and correction-specific variance, ensuring predictive intervals account for both global and local uncertainties. The Gaussian approximation is empirically validated for smooth solutions; see Appendix B for normality tests near sharp gradients. Together, Theorem 4.1 justifies learnable spectral encodings for controlling complexity, while Theorem 4.2 bounds calibration error for uncertainty quantification.

PINN	1.58e0	1.32e1	2.24e1	1.15e0
DeepONet	4.85e-2	3.72e-1	5.93e-1	3.28e-1
Rowdy	1.47e0	1.48e0	1.35e0	1.18e0
PDDLVM	3.54e-4	8.67e-4	2.15e-3	4.73e-3
GRNP	2.91e-4	7.23e-4	1.89e-3	3.96e-3
GP-HM	8.52e-5	4.95e-6	**2.24e-3**	1.05e-3
MF-PINP (Ours)	**7.12e-6**	**3.86e-6**	6.58e-3	**8.42e-4**

We test seven solutions spanning single-frequency ($u_1{=}\sin(100x)$), multi-frequency ($u_2{=}\sin(x){+}0.1\sin(20x){+}0.05\cos(100x)$, $u_3{=}\sin(6x)\cos(100x)$), and hybrid regimes ($u_4{=}x\sin(200x)$, $u_5{=}\sin(500x){-}2(x{-}0.5)^2$, $u_6{=}\sin(100x)\sin(100y)$, $u_7{=}\sin(6x)\sin(20x){+}\sin(6y)\sin(20y)$).

Allen-Cahn Equation (1D/2D).

$$u_{xx}+u(u^2-1)=f(x),\ x\in[0,2\pi];\qquad u_{xx}+u_{yy}+u(u^2-1)=f(x,y),\ (x,y)\in[0,1]^2. \tag{20}$$

Solutions: $u_1{=}\sin(100x)$, $u_2{=}\sin(6x)\cos(100x)$ (1D), and a 2D mixed-scale product solution.

Advection Equation (1D).

$$u_t+200u_x=0,\quad x\in[0,2\pi],\ t\in[0,1], \tag{21}$$

with analytical solution $u(x,t)=\sin(x-200t)$.

Burgers Equation (1D). $u_t{+}uu_x=\nu u_{xx}$, $\nu{=}0.01$, $u(x,0){=}-\sin(x)$, testing near-shock formation at low viscosity.

Navier-Stokes (2D). Vorticity formulation at Re$=500$ with three fidelity levels (32^2/128^2/256^2).

Data generation. Low-fidelity: finite differences on coarse grids ($N_0{=}500$ tasks); high-fidelity: spectral methods on fine grids ($N_1{=}50$ tasks). Context/target split: random 50/50. Each task corresponds to a distinct PDE parameter configuration.

5.2 Quantitative Comparison

We compare against seven single-fidelity baselines: Spectral-Feature NN Boyd (2001), PINN Karniadakis et al. (2021), DeepONet Lu et al. (2021), Rowdy Jagtap et al. (2022), PDDLVM Vadeboncoeur et al. (2022), GRNP Vadeboncoeur et al. (2023), GP-HM Fang et al. (2024); and four multi-fidelity baselines: MFNN Meng & Karniadakis (2020), MF-DeepONet Lu et al. (2022), MFRNP Niu et al. (2024), FNO Li et al. (2020a). All methods are evaluated using relative L^2 error $\|\hat{u}-u^*\|_2/\|u^*\|_2$, where $\hat{u}$ denotes the predicted solution and u^* is the ground truth.

Tables 1–2 report results on Poisson, Allen-Cahn, and Advection benchmarks. MF-PINP achieves the best performance on 9 of 11 test cases. The improvements are most dramatic on high-frequency solutions: on $u_1=\sin(100x)$, MF-PINP achieves 3.85×10^{-7} relative error, outperforming GP-HM (5.42×10^{-7}) and GRNP (3.18×10^{-4}) by $1.4\times$ and $827\times$ respectively. On the challenging multi-frequency $u_3=\sin(6x)\cos(100x)$, MF-PINP achieves 3.72×10^{-6} vs. GP-HM's 4.87×10^{-6}. For Allen-Cahn, MF-PINP achieves 7.12×10^{-6} on u_1, a $12\times$ improvement over GP-HM. Extended comparisons including multi-fidelity baselines and Navier-Stokes/Burgers results are in Appendix C.5.

Failure cases. MF-PINP underperforms on u_2 (1D Poisson) and 2D Allen-Cahn, where solutions are dominated by low frequencies and GP-HM's exact Bayesian inference provides tighter posteriors in moderate-data regimes ($N_1{=}50$). MF-PINP's advantages are most pronounced in data-scarce, high-frequency, and multi-scale settings.

Table 3: Ablation study: relative L^2 errors when removing key components. Best results in bold.

Variant	Poisson u_1	Poisson u_4	Poisson u_6	Allen-Cahn u_1	Advection
MF-PINP (Full)	**3.85e-7**	**1.18e-6**	**8.12e-5**	**7.12e-6**	**8.42e-4**
w/o LSE (σ=100)	8.93e-6	1.45e-5	1.52e-4	1.73e-5	1.89e-3
w/o PICA	1.52e-6	3.47e-6	1.45e-4	1.83e-5	1.52e-3
w/o HPR	2.94e-6	5.28e-6	2.18e-4	2.15e-5	2.37e-3
w/o ARC	8.67e-6	1.94e-5	3.52e-4	4.36e-5	4.18e-3

Table 4: Uncertainty quantification: coverage rate (nominal 95%), ECE, and interval width.

Method	**Coverage (%)**	**ECE**	**Width**
MF-PINP (Ours)	93.8	0.024	0.041
GP-HM	91.2	0.041	0.067
GRNP	85.7	0.089	0.038
MFRNP	89.4	0.052	0.055

5.3 Ablation Study

To validate each component, we systematically remove or replace: (1) learnable spectral encoding (LSE) vs. fixed Fourier features; (2) physics-informed cross-fidelity attention (PICA) vs. standard attention; (3) hierarchical physics regularization (HPR) vs. uniform weighting; (4) auto-regressive correction (ARC) vs. independent fidelity modeling.

All four components contribute: removing LSE increases error by over $127\times$ on high-frequency u_1; PICA reduces errors by up to 45% near sharp gradients; HPR yields 2–3$\times$ lower errors than uniform weighting; and ARC improves performance by 150–200% when high-fidelity data is scarce. Table 3 summarizes key results; full tables are in Appendix C.3.

5.4 Uncertainty Quantification

To validate Theorem 4.2, we evaluate predictive uncertainty using coverage rate (nominal 95%), expected calibration error (ECE), and average interval width. Table 4 summarizes results on representative benchmarks. MF-PINP achieves the best-calibrated uncertainty (93.8% coverage, closest to the 95% nominal) with the tightest intervals (ECE$= 0.024$). GRNP produces narrow intervals but severely under-covers (85.7%), reflecting overconfident predictions. GP-HM achieves reasonable coverage (91.2%) but with wider intervals, reflecting the cost of non-parametric flexibility.

5.5 Cross-Fidelity Generalization

A key advantage of multi-fidelity learning is generalization across resolution hierarchies and parameter domains. We evaluate through two experiments. In **fidelity interpolation**, we train on coarse (32×32) and fine (128×128) grids and evaluate on unseen intermediate resolutions (64×64, 96×96). MF-PINP achieves interpolation errors within 15% of training fidelity bounds, while single-fidelity baselines suffer 5–8$\times$ higher errors at unseen resolutions. In **parameter extrapolation**, we train on $\kappa \in [0.5, 2.0]$ and test on $\kappa \in [2.5, 4.0]$: MF-PINP degrades by only 28% (vs. 120–150% for single-fidelity methods), and uncertainty coverage remains near-nominal (94.6%) out-of-distribution, validating Theorem 4.2. Full protocols, quantitative metrics, and visualizations are in Appendix C.4.

6 Conclusion

We introduced MF-PINP, an adaptive spectral neural process for multi-fidelity PDE learning that combines hierarchical corrections, physics-informed cross-fidelity attention, and fidelity-adaptive regularization. PAC-Bayes and Berry-Esseen analyses provide generalization and calibration guarantees, while experiments demonstrate accurate cross-fidelity generalization with scarce high-fidelity data; limitations are discussed in Appendix A.5.

AI USE STATEMENT

Generative AI tools were used solely to assist with language polishing and figure preparation. All AI-assisted edits and visual materials were carefully reviewed and verified by the authors. The research ideas, problem formulation, methodology, theoretical analysis, experimental design, implementation, data, results, and conclusions are the authors' original work. Appendix

The appendix is organized as follows. Appendix A presents the training and inference algorithm, residual-gated architecture, training procedure, benchmark definitions, and limitations. Appendix B provides complete proofs of the generalization and uncertainty-calibration results. Appendix C reports the implementation environment and details, extended ablations, cross-fidelity generalization experiments, additional baseline comparisons, computational costs, and the Gaussian-modulation analysis.

A Technical Details

A.1 Algorithm

Algorithm 1 summarizes the training and inference procedures for MF-PINP. During training, we process multi-fidelity observations through hierarchical encoders with learnable spectral position encodings, aggregate information via physics-informed cross-fidelity attention, and optimize the complete objective combining data likelihood, physics residuals, and boundary constraints. At inference, the trained model generates predictions with calibrated uncertainties through auto-regressive corrections across fidelity levels.

Algorithm 1 MF-PINP Training and Inference for Multi-Fidelity PDE Learning

Input: Multi-fidelity datasets $\{\mathcal{C}_\ell, \mathcal{T}_\ell\}_{\ell=0}^{L-1}$, PDE operator $\mathcal{N}$, hyperparameters $\{\lambda_\ell, \lambda_{\text{PDE}}, \lambda_{\text{BC}}, \lambda_{\text{IC}}\}$
Output: Trained model parameters $\Theta = \{\Theta_{\text{spec}}, \Theta_{\text{enc}}, \Theta_{\text{dec}}\}$
Training Phase:
for epoch $= 1$ to T **do**
  for fidelity level $\ell = 0$ to $L-1$ **do**
    Compute spectral encodings $\phi_\ell(\mathbf{x}_i^{(\ell)})$ with learned frequencies $\{\boldsymbol{\mu}_q, w_q, \rho_q\}$
    Encode contexts: $\mathbf{h}_i^{(\ell)} = f_{\text{enc}}([\phi_\ell(\mathbf{x}_i^{(\ell)}), u_i^{(\ell)}, \theta, \mathbb{I}_\ell])$
    if $\ell = 0$ **then**
      Aggregate: $\mathbf{z}_0 \sim q(\mathbf{z}_0|\mathcal{C}_0)$ via mean pooling
    else
      Apply cross-fidelity attention: $\mathbf{z}_\ell \sim q(\mathbf{z}_\ell|\mathcal{C}_\ell, \mathbf{z}_{\ell-1})$
    end if
    Decode predictions: $\hat{u}_\ell = \rho_\ell \cdot \hat{u}_{\ell-1} + f_{\text{dec},\ell}([\phi_\ell(\mathbf{x}^*), \theta, \mathbf{z}_\ell])$
  end for
  Compute data loss: $\mathcal{L}_{\text{data}} = \sum_{\ell=0}^{L-1} \lambda_\ell \mathcal{L}_{\text{ELBO}}^{(\ell)}$
  Compute physics loss: $\mathcal{L}_{\text{PDE}} = \sum_{\ell=0}^{L-1} \tau_\ell \|\mathcal{N}[\hat{u}_\ell]\|^2$ on collocation points
  Compute constraint losses: $\mathcal{L}_{\text{BC}}, \mathcal{L}_{\text{IC}}$ at finest fidelity
  Total loss: $\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{data}} + \lambda_{\text{PDE}}\mathcal{L}_{\text{PDE}} + \lambda_{\text{BC}}\mathcal{L}_{\text{BC}} + \lambda_{\text{IC}}\mathcal{L}_{\text{IC}}$
  Update Θ via gradient descent
end for
Inference Phase:
Input: Query locations $\{\mathbf{x}_j^*\}$, context observations $\{\mathcal{C}_\ell\}_{\ell=0}^{L-1}$
for fidelity level $\ell = 0$ to $L-1$ **do**
  Encode contexts and aggregate into latent $\mathbf{z}_\ell$ via trained encoder
  Generate predictions: $\hat{u}_\ell(\mathbf{x}_j^*) = \rho_\ell \cdot \hat{u}_{\ell-1}(\mathbf{x}_j^*) + \delta_\ell(\mathbf{x}_j^*)$
end for
Return: Predictive mean $\mu_{L-1}(\mathbf{x}_j^*)$ and uncertainty $\sigma_{L-1}(\mathbf{x}_j^*)$

A.2 Architecture Details: Residual-Gated Fusion

The residual-gated fusion mechanism is presented in full in Section 3.3 of the main text. Briefly, cross-attention outputs are blended with self-aggregated representations via a learned gate $g_\ell = h_{\text{gate}}([\mathbf{z}_\ell^{\text{self}}, \bar{r}_{\text{PDE}}^{(\ell-1)}])$, where $\bar{r}_{\text{PDE}}^{(\ell-1)}$ is the average lower-fidelity PDE residual. This adaptive blending

ensures that when low-fidelity predictions are unreliable (high residual), the model relies more on current-level observations.

A.3 Training Details

Two-stage training. We first optimize only data terms $\mathcal{L}_{\text{ELBO}}^{(\ell)}$ to learn robust base representations, then gradually anneal in physics losses using cosine scheduling $\lambda_{\text{PDE}}(t) = \lambda_{\text{PDE}}^{\max} \cdot (1 - \cos(\pi t / T_{\text{anneal}}))/2$, preventing physics constraints from overwhelming data likelihood early in training.

Adaptive collocation sampling. After each epoch, collocation points are sampled proportional to $r_{\text{PDE}}(\mathbf{x})^2$ Wu et al. (2023), concentrating evaluations where the model violates physics constraints and substantially reducing collocation counts while maintaining equivalent physics enforcement.

Boundary/initial conditions. Enforced only at the finest fidelity $\ell = L - 1$ (see main text Eq. (8)) to avoid conflicts with coarse-grid inaccuracies.

A.4 Benchmark Problem Descriptions

We evaluate on five PDE families. **Poisson** (1D/2D): $u_{xx} = f(x)$ and $\Delta u = f(x, y)$ on $[0, 2\pi]^d$, with solutions $u_1 = \sin(100x)$, $u_2 = \sin(x) + 0.1\sin(20x) + 0.05\cos(100x)$, $u_3 = \sin(6x)\cos(100x)$, $u_4 = x\sin(200x)$, $u_5 = \sin(500x) - 2(x - 0.5)^2$, $u_6 = \sin(100x)\sin(100y)$, $u_7 = \sin(6x)\sin(20x) + \sin(6y)\sin(20y)$. **Allen-Cahn** (1D/2D): $u_{xx} + u(u^2 - 1) = f(x)$ and its 2D extension, with solutions $u_1 = \sin(100x)$, $u_2 = \sin(6x)\cos(100x)$, and a 2D mixed-scale product solution. **Advection** (1D): $u_t + 200u_x = 0$, solution $u(x, t) = \sin(x - 200t)$. **Burgers** (1D): $u_t + uu_x = \nu u_{xx}$, $\nu = 0.01$, $u(x, 0) = -\sin(x)$. **Navier-Stokes** (2D): vorticity formulation at Re$= 500$, three fidelity levels (32^2/128^2/256^2).

Low-fidelity: finite differences on coarse grids ($N_0 = 500$ tasks). High-fidelity: spectral methods on fine grids ($N_1 = 50$ tasks). Context/target split: random 50/50.

A.5 Limitations

(1) **Regular grids**: the spectral encoding module uses Fourier bases naturally defined on regular grids; extension to irregular domains requires geometry-aware alternatives (e.g., Laplacian eigenfunctions on meshes), though cross-fidelity attention and hierarchical regularization are domain-agnostic. (2) **Gaussian approximation**: Theorem 4.2 assumes approximate Gaussianity of latent corrections, validated empirically for smooth solutions (Shapiro-Wilk $p > 0.05$ at 94% of locations) but violated at $\sim$30% of locations near sharp gradients. (3) **Differentiable operators**: physics residuals require known, differentiable PDE operators via automatic differentiation, limiting applicability to black-box simulators.

B Proofs of Theoretical Results

B.1 Proof of Theorem 4.1: Generalization Bound for Spectral Neural Processes

We establish a PAC-Bayes generalization bound for neural processes equipped with learnable spectral position encodings under proper log-uniform priors. The proof proceeds in three steps: (1) applying the PAC-Bayes framework to relate expected risk to empirical risk plus KL divergence between learned and prior distributions, (2) bounding the Rademacher complexity of spectral encodings via covering number arguments, and (3) quantifying spectral truncation error using harmonic analysis.

Step 1: PAC-Bayes Decomposition. Let $\mathcal{D}$ denote the distribution over parametric PDE tasks $\tau = (\theta, \{(\mathbf{x}_i, u_i)\})$, where $\theta \in \Theta$ are PDE parameters and observations are sampled from solution fields. Given n training tasks $\{\tau_i\}_{i=1}^n \sim \mathcal{D}^n$, we learn a posterior distribution Q over model parameters $\Theta_{\text{model}} = \{\Theta_{\text{spec}}, \Theta_{\text{enc}}, \Theta_{\text{dec}}\}$ comprising spectral encoding parameters, encoder weights, and decoder weights.

The PAC-Bayes theorem (McAllester, 1999) states that for any prior distribution P over Θ_{model} that does not depend on the training data, with probability at least $1-\delta$ over the draw of training tasks:

$$\mathbb{E}_{\Theta\sim Q}[\mathcal{L}_{\mathcal{D}}(\Theta)] \leq \mathbb{E}_{\Theta\sim Q}\left[\frac{1}{n}\sum_{i=1}^{n}\mathcal{L}(\Theta;\tau_i)\right] + \sqrt{\frac{\mathrm{KL}(Q\|P)+\log(2n/\delta)}{2n}}, \tag{22}$$

where $\mathcal{L}_{\mathcal{D}}(\Theta) = \mathbb{E}_{\tau\sim\mathcal{D}}[\mathcal{L}(\Theta;\tau)]$ denotes the population risk, and $\mathrm{KL}(Q\|P)$ measures divergence between posterior and prior.

We decompose the prior P into independent components:

$$P(\Theta_{\text{model}}) = P_{\text{freq}}(\Theta_{\text{spec}}) \cdot P_{\text{NN}}(\Theta_{\text{enc}}, \Theta_{\text{dec}}), \tag{23}$$

where P_{freq} is the truncated log-uniform prior over spectral parameters and P_{NN} is a Gaussian prior over neural network weights. The KL divergence decomposes accordingly:

$$\mathrm{KL}(Q\|P) = \mathrm{KL}(Q_{\text{freq}}\|P_{\text{freq}}) + \mathrm{KL}(Q_{\text{NN}}\|P_{\text{NN}}). \tag{24}$$

For the truncated log-uniform prior P_{freq} with $p(w_q) = 1/(w_q \log(w_{\max}/\epsilon))$ for $w_q \in [\epsilon, w_{\max}]$ (where $\epsilon = 10^{-6}$, $w_{\max} = 10^2$) over frequency weights and uniform priors over $\boldsymbol{\mu}_q, \rho_q$ within bounded ranges, the learned posterior concentrates mass on a subset of active frequencies. Let $\mathcal{A} = \{q : w_q > \epsilon\}$ denote the set of active frequency components. The KL divergence can be bounded as:

$$\mathrm{KL}(Q_{\text{freq}}\|P_{\text{freq}}) \leq |\mathcal{A}| \log(\log(w_{\max}/\epsilon)) + \sum_{q\in\mathcal{A}} \left|\log(w_q/w_q^*)\right|, \tag{25}$$

where w_q^* denotes the posterior mode for component q. The log-uniform prior penalizes small weights through the $\log(1/w_q)$ density shape, inducing sparsity while remaining proper and ensuring finite KL divergence.

Step 2: Rademacher Complexity of Spectral Encodings. To bound the neural network component $\mathrm{KL}(Q_{\text{NN}}\|P_{\text{NN}})$, we relate it to the Rademacher complexity of the function class. The Rademacher complexity of a hypothesis class $\mathcal{H}$ on a sample $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^m$ is:

$$\mathfrak{R}_S(\mathcal{H}) = \mathbb{E}_{\boldsymbol{\sigma}}\left[\sup_{h\in\mathcal{H}} \frac{1}{m}\sum_{i=1}^{m}\sigma_i h(\mathbf{x}_i)\right], \tag{26}$$

where $\sigma_i \in \{-1, +1\}$ are independent Rademacher random variables.

For neural networks with spectral position encodings, each layer applies compositions of the form $h^{(\ell+1)} = \phi(W^{(\ell)}h^{(\ell)})$ where ϕ is a Lipschitz activation and $h^{(0)} = [\phi_{\text{spec}}(\mathbf{x}), u(\mathbf{x}), \theta]$ concatenates spectral features with observations. The key insight is that spectral encodings with learned frequencies have bounded variation controlled by the frequency components.

For a spectral encoding $\phi_{\text{spec}}(\mathbf{x}) = \sum_{q=1}^{Q} w_q \exp(-\|\mathbf{x}\|^2/(2\rho_q^2)) \cdot [\cos(2\pi\boldsymbol{\mu}_q^\top\mathbf{x}), \sin(2\pi\boldsymbol{\mu}_q^\top\mathbf{x})]$, the Lipschitz constant with respect to $\mathbf{x}$ is:

$$L_\phi \leq \sum_{q=1}^{Q} w_q \left(\frac{1}{\rho_q} + 2\pi\|\boldsymbol{\mu}_q\|\right)\exp(-\|\mathbf{x}\|^2/(2\rho_q^2)). \tag{27}$$

Under the assumption that spatial domain is compact $\Omega \subset [-R, R]^{d_x}$ and frequencies are bounded $\|\boldsymbol{\mu}_q\| \leq f_{\max}$, we have:

$$L_\phi \leq \sum_{q=1}^{Q} w_q \left(\frac{1}{\rho_{\min}} + 2\pi f_{\max}\right) =: C_\phi \sum_{q=1}^{Q} w_q, \tag{28}$$

where $\rho_{\min} = \min_q \rho_q$. The log-uniform prior encourages small $\sum_q w_q$ by penalizing large weights, thus controlling L_ϕ.

By standard Rademacher complexity bounds for Lipschitz compositions (Bartlett et al., 2017), for a depth-D network with layer widths $\{d_\ell\}_{\ell=1}^{D}$ and spectral layer norm bounds $\|W^{(\ell)}\|_2 \le B_\ell$:

$$\mathfrak{R}_S(\mathcal{H}_{\text{spec}}) \le C_\phi \left(\sum_{q=1}^{Q} w_q\right) \prod_{\ell=1}^{D} B_\ell \cdot \sqrt{\frac{d_z \log d_{\max}}{m}}, \tag{29}$$

where $d_{\max} = \max_\ell d_\ell$ and d_z is the latent dimension. Connecting Rademacher complexity to generalization via standard learning theory results (Mohri et al., 2018):

$$\mathbb{E}_{\tau\sim\mathcal{D}}[\mathcal{L}(\hat{f}_\tau)] \le \frac{1}{n}\sum_{i=1}^{n} \mathcal{L}(\hat{f}_{\tau_i}) + 2\mathfrak{R}_n(\mathcal{H}_{\text{spec}}) + \mathcal{O}\left(\sqrt{\frac{\log(1/\delta)}{n}}\right). \tag{30}$$

Substituting the Rademacher complexity bound and noting that the log-uniform prior controls $\sum_q w_q$ through the KL term, we obtain:

$$\text{KL}(Q_{\text{NN}} \| P_{\text{NN}}) \le \mathcal{O}\left(d_z \log n\right), \tag{31}$$

under typical Gaussian prior assumptions on network weights.

Step 3: Spectral Truncation Error. Finally, we quantify the approximation error $\epsilon_{\text{trunc}}(Q)$ incurred by truncating the spectral representation to Q frequency components. For a target function $u(\mathbf{x})$ in the Sobolev space $H^s(\Omega)$ with smoothness index $s > d_x/2$, its Fourier series representation is:

$$u(\mathbf{x}) = \sum_{\mathbf{k}\in\mathbb{Z}^{d_x}} \hat{u}(\mathbf{k}) e^{2\pi i \mathbf{k}^\top \mathbf{x}}, \tag{32}$$

with Fourier coefficients $\hat{u}(\mathbf{k})$ satisfying $\sum_{\mathbf{k}} (1 + \|\mathbf{k}\|^2)^s |\hat{u}(\mathbf{k})|^2 < \infty$.

When approximating with Q frequency components selected by the learned distribution $q_{\text{freq}}(\boldsymbol{\mu}_q)$, the L^2 approximation error is:

$$\epsilon_{\text{trunc}}(Q) = \left\| u - \sum_{q=1}^{Q} w_q \phi_q \right\|_{L^2(\Omega)} \le \left(\sum_{\mathbf{k}\notin\mathcal{S}_Q} |\hat{u}(\mathbf{k})|^2 \right)^{1/2}, \tag{33}$$

where $\mathcal{S}_Q$ is the set of Q frequency modes $\mathbf{k}$ with largest $|\hat{u}(\mathbf{k})|^2$. By Sobolev embedding, the tail sum decays as:

$$\sum_{\mathbf{k}\notin\mathcal{S}_Q} |\hat{u}(\mathbf{k})|^2 \le C_s \sum_{\|\mathbf{k}\|>K_Q} \|\mathbf{k}\|^{-2s}, \tag{34}$$

where $K_Q \sim Q^{1/d_x}$ is the frequency radius containing Q modes. For $s > d_x/2$, this sum converges as:

$$\epsilon_{\text{trunc}}(Q) \le C_s K_Q^{d_x - 2s} = \mathcal{O}(Q^{-s/d_x + 1/2}). \tag{35}$$

For sufficient smoothness $s \ge d_x$, we obtain $\epsilon_{\text{trunc}}(Q) = \mathcal{O}(Q^{-1/2})$ as stated.

Combining the Bounds. Assembling Eqs. (22), (25), (31), and the spectral truncation analysis:

$$\begin{aligned}\mathbb{E}_{\tau\sim\mathcal{D}}[\mathcal{L}(\hat{f}_\tau)] \le & \frac{1}{n}\sum_{i=1}^{n} \mathcal{L}(\hat{f}_{\tau_i}) + \sqrt{\frac{2\text{KL}(Q_{\text{freq}} \| P_{\text{freq}})}{n}} \\ & + \mathcal{O}\left(\sqrt{\frac{d_z \log n}{n}}\right) + \epsilon_{\text{trunc}}(Q) + \mathcal{O}\left(\sqrt{\frac{\log(1/\delta)}{n}}\right).\end{aligned} \tag{36}$$

Absorbing lower-order terms completes the proof of Theorem 4.1.

B.2 Proof of Theorem 4.2: Hierarchical Uncertainty Calibration

We establish that the auto-regressive hierarchical decoder produces approximately calibrated predictive intervals whose coverage probabilities converge to nominal confidence levels, with calibration error bounded by $\mathcal{O}(1/\sqrt{N_{\min}})$.

Setup and Assumptions. Recall the hierarchical decoder from Eq. (6):

$$\hat{u}_\ell(\mathbf{x}^*) = \rho_\ell \cdot \hat{u}_{\ell-1}(\mathbf{x}^*) + \delta_\ell(\mathbf{x}^*), \quad \ell = 1, \ldots, L-1, \tag{37}$$

with base prediction $\hat{u}_0(\mathbf{x}^*)$ and correction terms $\delta_\ell(\mathbf{x}^*)$ output by decoders conditioned on latent codes $\mathbf{z}_\ell$. Crucially, $\delta_\ell(\mathbf{x}^*) = f_{\text{dec},\ell}([\phi_\ell(\mathbf{x}^*), \theta, \mathbf{z}_\ell]; \Theta_{\text{dec},\ell})$ is a deterministic function of its inputs—all stochasticity in the predictive distribution arises from the latent variables $\mathbf{z}_\ell \sim q(\mathbf{z}_\ell|\mathcal{C}_\ell, \mathbf{z}_{\ell-1})$. The predictive mean and variance at each fidelity level are obtained by marginalizing over the latent posterior:

$$\mu_\ell(\mathbf{x}^*) = \mathbb{E}_{\mathbf{z}_\ell}[\hat{u}_\ell(\mathbf{x}^*)], \tag{38}$$

$$\sigma^2_\ell(\mathbf{x}^*) = \text{Var}_{\mathbf{z}_\ell}[\hat{u}_\ell(\mathbf{x}^*)]. \tag{39}$$

We make the following conditional independence assumption:

Assumption B.1 (Conditional Independence of Corrections)**.** *Given latent code $\mathbf{z}_\ell$, the correction term $\delta_\ell(\mathbf{x}^*)$ is independent of lower-fidelity prediction $\hat{u}_{\ell-1}(\mathbf{x}^*)$:*

$$\delta_\ell(\mathbf{x}^*) \perp \hat{u}_{\ell-1}(\mathbf{x}^*) \mid \mathbf{z}_\ell. \tag{40}$$

This assumption is reasonable when decoders at level ℓ condition on sufficient statistics $\mathbf{z}_\ell$ that capture all relevant information from contexts $\mathcal{C}_\ell$ and inherited structure $\mathbf{z}_{\ell-1}$.

Predictive Distribution at Highest Fidelity. Under the auto-regressive structure and Assumption B.1, the predictive distribution at the highest fidelity $L-1$ is approximately Gaussian by the central limit theorem applied to the aggregation of independent latent contributions:

$$\hat{u}_{L-1}(\mathbf{x}^*) \approx \mathcal{N}(\mu_{L-1}(\mathbf{x}^*), \sigma^2_{L-1}(\mathbf{x}^*)), \tag{41}$$

where the mean and variance are computed recursively:

$$\mu_{L-1}(\mathbf{x}^*) = \rho_{L-1}\mu_{L-2}(\mathbf{x}^*) + \mu_\delta^{L-1}(\mathbf{x}^*), \tag{42}$$

$$\sigma^2_{L-1}(\mathbf{x}^*) = \rho^2_{L-1}\sigma^2_{L-2}(\mathbf{x}^*) + \sigma_\delta^{L-1,2}(\mathbf{x}^*). \tag{43}$$

Expanding recursively to the base level:

$$\mu_{L-1}(\mathbf{x}^*) = \left(\prod_{\ell=1}^{L-1} \rho_\ell\right) \mu_0(\mathbf{x}^*) + \sum_{\ell=1}^{L-1} \left(\prod_{j=\ell+1}^{L-1} \rho_j\right) \mu_\delta^\ell(\mathbf{x}^*), \tag{44}$$

with the convention that empty products equal 1. Similarly:

$$\sigma^2_{L-1}(\mathbf{x}^*) = \left(\prod_{\ell=1}^{L-1} \rho^2_\ell\right) \sigma^2_0(\mathbf{x}^*) + \sum_{\ell=1}^{L-1} \left(\prod_{j=\ell+1}^{L-1} \rho^2_j\right) \sigma_\delta^{\ell,2}(\mathbf{x}^*). \tag{45}$$

Calibration via Berry-Esseen Bound. For a nominal confidence level $\alpha \in (0,1)$, the $(1-\alpha)$-level predictive interval is:

$$I_\alpha(\mathbf{x}^*) = \left[\mu_{L-1}(\mathbf{x}^*) - z_{\alpha/2}\sigma_{L-1}(\mathbf{x}^*), \mu_{L-1}(\mathbf{x}^*) + z_{\alpha/2}\sigma_{L-1}(\mathbf{x}^*)\right], \tag{46}$$

where $z_{\alpha/2} = \Phi^{-1}(1-\alpha/2)$ is the standard normal quantile. We bound the calibration error:

$$|\mathbb{P}(u_{L-1}(\mathbf{x}^*) \in I_\alpha(\mathbf{x}^*)) - (1-\alpha)| \leq \frac{C_{\text{BE}} \cdot M_3}{\sigma^3_{\min}\sqrt{N_{\min}}} + \epsilon_{\text{var}}. \tag{47}$$

The coverage probability depends on how well the model's predictive mean $\mu_{L-1}(\mathbf{x}^*)$ and variance $\sigma^2_{L-1}(\mathbf{x}^*)$ match the true conditional distribution. By the law of large numbers, as context set sizes $N_\ell \to \infty$, the empirical aggregation in Eq. (3) converges to population statistics:

$$\boldsymbol{\mu}_\ell \xrightarrow{p} \mathbb{E}[\mathbf{h}_i^{(\ell)}], \quad \mathbf{s}_\ell \xrightarrow{p} \mathbb{E}[(\mathbf{h}_i^{(\ell)})^2], \tag{48}$$

where convergence is in probability. By the delta method, the neural network mappings g_{μ_ℓ} and g_{Σ_ℓ} yield consistent estimators of conditional mean and variance parameters.

For Gaussian predictive distributions, the coverage error is controlled by the deviation of estimated moments from true moments. Applying the Berry-Esseen theorem to bound the rate of convergence in the central limit theorem:

$$\sup_{\mathbf{x}^*} \left| \mathbb{P}\left(\frac{u_{L-1}(\mathbf{x}^*) - \mu_{L-1}(\mathbf{x}^*)}{\sigma_{L-1}(\mathbf{x}^*)} \leq z \right) - \Phi(z) \right| \leq \frac{C\mathbb{E}[|\mathbf{h}|^3]}{(\min_\ell \text{Var}[\mathbf{h}^{(\ell)}])^{3/2}\sqrt{N_{\min}}}, \tag{49}$$

where C is an absolute constant and $N_{\min} = \min_\ell N_\ell$ is the smallest context set size across fidelities.

Under standard boundedness assumptions on embeddings $\mathbf{h}_i^{(\ell)}$ (e.g., from bounded activation functions), the third moment $\mathbb{E}[|\mathbf{h}|^3]$ is finite, yielding:

$$|\mathbb{P}(u_{L-1}(\mathbf{x}^*) \in I_\alpha(\mathbf{x}^*)) - (1-\alpha)| = \mathcal{O}\left(\frac{1}{\sqrt{N_{\min}}}\right), \tag{50}$$

as claimed.

Uncertainty Propagation Across Fidelities. The hierarchical variance decomposition in Eq. (45) reveals how uncertainties accumulate: base variance $\sigma_0^2(\mathbf{x}^*)$ from coarse simulations is amplified by squared scaling factors $\prod_\ell \rho_\ell^2$, while each correction adds independent variance $\sigma_\delta^{\ell,2}(\mathbf{x}^*)$ weighted by subsequent scalings. This additive structure ensures that total uncertainty increases monotonically with refinement unless corrections drastically reduce variance, which would violate the principle that finer resolutions reveal previously unresolved features.

In practice, learned scaling parameters $\rho_\ell \approx 1$ when lower fidelities provide accurate global structure, and $\sigma_\delta^{\ell,2}(\mathbf{x}^*)$ quantifies refinement uncertainty. The model automatically learns these components from data, producing calibrated intervals that reflect both inherited and correction-specific uncertainties.

Finite-Sample Guarantees. For finite context sets, we can derive non-asymptotic calibration guarantees using empirical Bernstein inequalities. With probability at least $1-\delta$ over context samples, the deviation of estimated variance from true variance is bounded as:

$$\left|\hat{\sigma}_\ell^2(\mathbf{x}^*) - \sigma_\ell^2(\mathbf{x}^*)\right| \leq \sqrt{\frac{2V\log(2/\delta)}{N_\ell}} + \frac{3M\log(2/\delta)}{N_\ell}, \tag{51}$$

where V bounds the variance of squared residuals and M bounds embedding magnitudes. Combining across fidelities using union bounds:

$$\mathbb{P}\left(\forall \ell : \left|\hat{\sigma}_\ell^2(\mathbf{x}^*) - \sigma_\ell^2(\mathbf{x}^*)\right| \leq \epsilon_\ell\right) \geq 1 - L\delta, \tag{52}$$

where $\epsilon_\ell = \mathcal{O}(1/\sqrt{N_\ell})$. This yields high-probability calibration guarantees with explicit dependence on context set sizes.

Combining these results completes the proof of Theorem 4.2. □

Empirical Validation of Normality Assumption. We validate the Gaussian approximation underlying Theorem 4.2 using Shapiro-Wilk tests on the standardized prediction errors $(u(\mathbf{x}^*) - \mu_{L-1}(\mathbf{x}^*))/\sigma_{L-1}(\mathbf{x}^*)$ across spatial locations. For smooth solutions (Poisson u_1, Diffusion), normality holds well ($p > 0.05$ for 94% of spatial locations). Near sharp gradients (Allen-Cahn interface regions), normality is violated at approximately 30% of locations, where correction terms exhibit heavier tails. This suggests that Theorem 4.2's bound is tightest for smooth PDE solutions and may underestimate calibration error near discontinuities. In such regimes, distribution-free alternatives (e.g., conformal prediction) may provide more reliable coverage guarantees.

C Additional Experimental Details and Results

C.1 Hardware and Software Configuration

To ensure the reproducibility and reliability of the experiments conducted in this study, we detail the hardware and software environments used.

- **GPU Model(s):**
  - Model: NVIDIA RTX 4090
  - Count: 8 GPUs
  - Memory per GPU: 16 GB
- **CPU Model(s):**
  - Model: Intel(R) Xeon(R) Silver 4416+
  - Core Count: 40
- **Operating System:**
  - OS: Ubuntu 22.04.5 LTS
  - Kernel Version: 5.15.0-142-generic
- **Relevant Software Libraries and Frameworks:**
  - CUDA: Version 11.8
  - cuDNN: Version 8.6
  - PyTorch: Version 2.0.0
  - Scikit-learn: Version 1.5.0
  - NumPy: Version 1.26.3
  - Pandas: Version 2.2.2

C.2 Implementation Details

MF-PINP uses spectral encodings with $Q = 30$ learnable frequency components, 8-head cross-fidelity attention, latent dimension $d_z = 128$. Encoders/decoders are 4-layer MLPs (256 hidden units, LayerNorm, GELU activations). Training via Adam optimizer (lr $= 10^{-3}$, cosine annealing) for 50k iterations per task distribution, batch size 32 tasks. Physics loss weight λ_{PDE} annealed from 0 to 1.0 over first 20k steps. Collocation points: $N_{\text{col}}^{(0)} = 64$, $N_{\text{col}}^{(1)} = 256$. Boundary loss weight $\lambda_{\text{BC}} = 10$.

C.3 Detailed Ablation Study

In this appendix, we provide comprehensive details of our ablation experiments to validate the contribution of each key component in the MF-PINP framework.

Experimental Setup. We systematically remove or replace four critical components and evaluate their impact on prediction accuracy across our benchmark problems:

First, for learnable spectral encoding (LSE), we compare our learnable spectral position encoding with log-uniform priors against fixed Fourier features with predetermined frequency matrices sampled from $\mathcal{N}(0, \sigma^2\mathbf{I})$ where $\sigma \in \{1, 10, 100\}$.

Second, for physics-informed cross-attention (PICA), we replace our physics-informed cross-fidelity attention mechanism with standard scaled dot-product attention without spatial bias or PDE residual weighting.

Third, for hierarchical physics regularization (HPR), we compare our fidelity-adaptive physics loss with decreasing tolerance weights $\tau_\ell = \tau_0 \cdot 2^{-\ell}$ against uniform weighting $\tau_\ell = \tau_0$ across all fidelity levels.

Fourth, for auto-regressive correction (ARC), we ablate the hierarchical correction structure by training independent neural processes for each fidelity level without cross-fidelity information sharing.

Main Results. Table 5 presents the relative L^2 errors for different ablated variants on representative benchmark problems. The full MF-PINP model consistently achieves the best performance across all test cases. Removing learnable spectral encoding results in significant performance degradation, particularly on high-frequency solutions (u_1, u_4) where fixed Fourier features fail to capture the appropriate frequency content. The impact is most pronounced on the Poisson equation with $u_1 = \sin(100x)$, where replacing LSE increases the error by $127\times$ (from 3.85e-7 to 4.89e-5).

Table 5: Ablation study results showing relative L^2 errors when removing key components from MF-PINP. Each row represents a variant where one component is removed or replaced. Best results are in bold.

w/o ARC	6.93e-4	3.51e-4	1.89e-4
Relative Increase	$+181\%$	$+160\%$	$+133\%$

The physics-informed cross-attention mechanism proves essential for problems with discontinuities or sharp gradients. Without spatial locality bias and PDE residual weighting, the model struggles to appropriately fuse information across fidelity levels, leading to up to 45% error increase on the Allen-Cahn equation. Hierarchical physics regularization demonstrates its importance by adapting constraint enforcement to resolution-dependent discretization errors. Using uniform physics weights causes the model to over-regularize coarse predictions or under-regularize fine predictions, resulting in $2 - 3\times$ higher errors on average.

The auto-regressive correction structure shows dramatic impact when high-fidelity data is scarce. Independent modeling of each fidelity level fails to leverage the abundant low-fidelity observations, increasing errors by $50 - 200\%$ depending on the problem complexity. This validates our core hypothesis that explicitly modeling hierarchical corrections is crucial for efficient multi-fidelity learning.

Data Efficiency Analysis. To further investigate the impact of the auto-regressive structure under varying data availability, we conduct an additional experiment where we train variants with 5, 10, and 20 high-fidelity observations while keeping 500 low-fidelity samples fixed. Table 6 shows that the performance gap between full MF-PINP and the variant without auto-regressive correction (w/o ARC) widens dramatically as high-fidelity data becomes scarcer. With only 5 high-fidelity samples, removing the hierarchical correction increases error by over 180%, demonstrating that explicit cross-fidelity modeling is most critical in the data-scarce regime that motivates multi-fidelity learning.

C.4 Cross-Fidelity Generalization Analysis

Experimental Setup Fidelity Interpolation. We train MF-PINP using only two fidelity levels: coarse resolution (32×32 grid, $N_0 = 500$ samples) and fine resolution (128×128 grid, $N_2 = 50$ samples). The intermediate fidelity level (64×64 grid) is deliberately excluded from training. At inference, we evaluate predictions at unseen resolutions 64×64 and 96×96 to assess interpolation capability. Ground truth solutions are computed using high-accuracy spectral methods with 256×256

grids for 2D problems. We compare against single-fidelity methods (PINN, DeepONet, GRNP) trained separately on each resolution, and multi-fidelity baselines (PDDLVM, GP-HM) trained on the same two-level hierarchy.

Parameter Extrapolation. We focus on the parametric 2D diffusion equation $\partial u/\partial t = \kappa \nabla^2 u + f(x, y, t)$ where diffusion coefficient κ controls spatial smoothing. Training data uses $\kappa \in [0.5, 2.0]$ sampled at 20 values ($N_{\text{train}} = 500$ low-fidelity, $N_{\text{train}} = 50$ high-fidelity per parameter). We evaluate on out-of-distribution parameters $\kappa \in [2.5, 4.0]$ sampled at 10 values, representing 25-100% shift beyond the training range. For each method, we train two variants: (1) standard data-driven without PDE loss, and (2) physics-informed with $\mathcal{L}_{\text{PDE}}$. We compute prediction accuracy (relative L^2 error), uncertainty calibration (95% coverage rate), and extrapolation degradation ratio (OOD error / in-distribution error).

Fidelity Interpolation Results Table 7 presents relative L^2 errors across test resolutions for the 2D Poisson equation ($u_6 = \sin(100x)\sin(100y)$). Multi-fidelity methods significantly outperform single-fidelity approaches, with MF-PINP achieving 0.35% error at 64×64 interpolation compared to 1.87-2.68% for single-fidelity baselines (5-8× improvement). MF-PINP demonstrates smooth interpolation: errors at intermediate resolutions (0.35% at 64^2, 0.30% at 96^2) fall strictly between coarse (0.52%) and fine (0.28%) training errors, validating the auto-regressive correction mechanism. Single-fidelity methods show poor cross-resolution transfer, with fine-trained models degrading substantially when applied to coarse grids (e.g., PINN-Fine at 32^2: 4.82%).

Table 7: Fidelity interpolation errors (%) for 2D Poisson equation. Methods are trained on 32×32 and 128×128 grids only. Columns show performance on unseen intermediate resolutions.

Method	**Training Res.**		**Test Resolution**		
	32^2	128^2	64^2 (Interp.)	96^2 (Interp.)	128^2
Single-Fidelity Methods					
PINN-Coarse	2.38	2.15	2.24	2.18	2.15
PINN-Fine	4.82	1.85	3.12	2.28	1.85
PINN-Averaged	3.60	2.00	2.68	2.23	2.00
DeepONet-Coarse	1.94	1.78	1.86	1.81	1.78
DeepONet-Fine	3.25	0.92	1.89	1.24	0.92
DeepONet-Averaged	2.59	1.35	1.87	1.52	1.35
GRNP-Coarse	2.12	1.93	2.02	1.97	1.93
GRNP-Fine	3.58	1.15	2.18	1.52	1.15
GRNP-Averaged	2.85	1.54	2.10	1.74	1.54
Multi-Fidelity Methods					
PDDLVM	0.82	0.45	0.58	0.49	0.45
GP-HM	0.68	0.38	0.47	0.41	0.38
MF-PINP (Ours)	**0.52**	**0.28**	**0.35**	**0.30**	**0.28**

Table 8 extends these results across all benchmark PDE families, showing consistent interpolation advantages: MF-PINP achieves ∼0.35-0.54% errors at 64×64 interpolation across problems, representing 3-5× improvements over single-fidelity baselines and 35-40% improvements over multi-fidelity competitors.

Parameter Extrapolation Results Table 9 compares extrapolation performance on the parametric diffusion equation. We report average errors over 10 out-of-distribution κ values and compute degradation ratios relative to in-distribution performance. Physics-informed constraints substantially improve extrapolation robustness: incorporating $\mathcal{L}_{\text{PDE}}$ reduces degradation ratios by 20-35% across all methods. MF-PINP with physics achieves only 1.28× degradation (from 0.26% to 0.45% error), compared to 1.79-1.93× for single-fidelity physics-informed methods and 2.50-2.59× for data-driven single-fidelity approaches. Multi-fidelity learning enhances robustness even without physics constraints: data-driven MF-PINP (2.07× degradation) outperforms data-driven single-fidelity methods (2.50-2.59×), suggesting hierarchical representations capture generalizable structures.

Table 8: Fidelity interpolation errors (%) across benchmark problems at 64×64 test resolution (trained on 32^2 and 128^2 only).

GP-HM	0.47	0.72	0.61
MF-PINP (Ours)	**0.35**	**0.54**	**0.48**

Uncertainty calibration degrades less for MF-PINP: coverage rates remain near nominal 95% level for MF-PINP + Physics (94.6% out-of-distribution) while single-fidelity methods drop to 78-86%, indicating overconfident predictions under distribution shift. This validates Theorem 4.2's guarantee that hierarchical uncertainty propagation maintains reliability across parameter domains.

Table 9: Parameter extrapolation results for diffusion equation with $\kappa \in [2.5, 4.0]$ (trained on $\kappa \in [0.5, 2.0]$). Columns show in-distribution error, out-of-distribution error, degradation ratio, and uncertainty coverage rate.

Method	Rel. L^2 Error (%)		Degradation	Coverage (%)
	In-Dist.	OOD		
Data-Driven (No Physics Loss)				
PINN	1.85	4.62	2.50×	78.3
DeepONet	0.92	2.38	2.59×	81.5
GRNP	1.15	2.87	2.50×	84.2
PDDLVM	0.45	0.98	2.18×	87.6
GP-HM	0.38	0.82	2.16×	89.1
MF-PINP	0.28	0.58	2.07×	91.3
Physics-Informed (With $\mathcal{L}_{PDE}$)				
PINN + Physics	1.68	3.24	1.93×	82.7
DeepONet + Physics	0.85	1.52	1.79×	86.3
GRNP + Physics	1.02	1.78	1.75×	88.5
PDDLVM + Physics	0.41	0.63	1.54×	91.2
GP-HM + Physics	0.35	0.52	1.49×	92.8
MF-PINP + Physics	**0.26**	**0.45**	**1.28×**	**94.6**

The fidelity interpolation capability enables practitioners to query MF-PINP at arbitrary resolutions without retraining, adapting to computational budgets at inference time. Interpolation errors (0.35% at 64^2 for 2D Poisson) fall within 15% of training fidelity bounds, validating smooth hierarchical corrections. Parameter extrapolation results demonstrate that physics-informed multi-fidelity learning achieves 28% error increase under distribution shift, compared to 120-150% degradation for single-fidelity methods. Preserved uncertainty calibration (94.6% coverage out-of-distribution) supports Theorem 4.2's theoretical guarantees. These results confirm that auto-regressive correction mechanisms generalize across unseen fidelity levels and parameter domains, with physics constraints providing additional robustness.

C.5 Extended Baseline Comparisons

We provide extended comparisons against multi-fidelity baselines on all benchmark problems, including the newly added Burgers and Navier-Stokes equations.

Multi-Fidelity Baselines on Core Benchmarks. Table 10 presents relative L^2 errors comparing MF-PINP against dedicated multi-fidelity methods on representative benchmarks. All multi-fidelity methods use identical data budgets ($N_0 = 500$ low-fidelity, $N_1 = 50$ high-fidelity tasks).

MF-PINP consistently outperforms all multi-fidelity baselines. Compared to the strongest competitor MFRNP, MF-PINP achieves 3.0× improvement on 2D Poisson, 4.0× on Allen-Cahn, and 1.9× on

Table 10: Relative L^2 errors comparing multi-fidelity methods across benchmark problems. All methods use identical multi-fidelity data budgets.

Method	Poisson u_6 (2D)	Allen-Cahn u_1	Advection	Burgers (ν=0.01)
MFNN	1.53e-3 ± 2.1e-4	2.41e-4 ± 1.8e-5	8.23e-3 ± 1.5e-3	6.87e-2 ± 1.2e-3
MFPC-Net	3.26e-2 ± 2.4e-2	3.94e-2 ± 1.7e-2	3.51e-2 ± 2.3e-2	2.64e-1 ± 1.9e-2
MF-DeepONet	4.13e-4 ± 2.6e-5	5.17e-5 ± 2.1e-6	2.28e-3 ± 1.7e-4	1.15e-3 ± 1.3e-4
MFRNP	2.47e-4 ± 1.8e-5	2.83e-5 ± 1.6e-6	1.63e-3 ± 1.2e-4	1.82e-3 ± 1.4e-4
FNO	3.89e-4 ± 3.2e-5	4.52e-5 ± 2.8e-6	1.95e-3 ± 2.1e-4	8.74e-4 ± 9.5e-5
MF-PINP (Ours)	**8.12e-5** ± 1.3e-5	**7.12e-6** ± 1.1e-6	**8.42e-4** ± 1.5e-4	**3.47e-4** ± 2.3e-5

Advection. The improvement is most pronounced on problems with multi-scale features, validating the contribution of learnable spectral encodings. MFPC-Net performs poorly due to its fixed physics constraints that cannot adapt to fidelity-dependent discretization errors.

Navier-Stokes Results. Table 11 presents results on the 2D Navier-Stokes benchmark (Re = 500), which represents a significantly more challenging and realistic test case with turbulent dynamics.

Table 11: Results on 2D Navier-Stokes (Re = 500, vorticity formulation) with three fidelity levels. Relative L^2 error and uncertainty coverage (95% nominal) are reported.

Method	Rel. L^2 Error	Coverage (95%)
PINN	1.24e-1	—
DeepONet	8.91e-2	—
FNO	4.12e-2	—
GRNP	6.34e-2	83.4%
MF-DeepONet	3.87e-2	—
MFRNP	3.15e-2	86.7%
MF-PINP (Ours)	**2.47e-2**	**92.1%**

On this challenging benchmark, MF-PINP achieves 2.47% relative error, outperforming FNO (4.12%) and MFRNP (3.15%). The physics-informed cross-fidelity attention is particularly beneficial here, as the PDE residual weighting helps identify regions where coarse simulations poorly resolve vortex dynamics. Uncertainty coverage (92.1%) remains close to the 95% nominal level despite the complexity of turbulent flows.

Stronger PINN Baselines. We additionally compare against recent PINN variants designed for multi-scale PDEs:

Table 12: Comparison with advanced PINN variants on selected benchmarks. Note that PINN variants solve single PDE instances (re-trained per configuration), while MF-PINP performs amortized inference across the parametric family.

Method	Poisson u_3	Allen-Cahn u_1	Advection
Multi-scale PINN	5.8e-3	1.23e-2	7.1e-3
Fourier-feature PINN	4.9e-3	9.8e-3	5.8e-3
GRNP	7.2e-3	1.56e-2	9.2e-3
MF-PINP (Ours)	**3.1e-3**	**4.5e-3**	**2.1e-3**

C.6 Model Complexity and Computational Cost

Parameter Counts. Table 13 reports the number of trainable parameters for each method. Among operator-learning methods, MF-PINP (1.82M) is comparable to DeepONet (1.65M) and GRNP (1.74M), confirming that performance gains stem from architectural design rather than capacity advantage.

Table 13: Number of trainable parameters for each method.

Method	Parameters
PINN	0.26M
DeepONet	1.65M
FNO	2.37M
GRNP	1.74M
MFRNP	1.89M
MF-DeepONet	1.78M
GP-HM	N/A (non-parametric)
MF-PINP (Ours)	1.82M

Runtime Comparison. Table 14 compares training time, inference latency, and data generation cost assumptions.

Table 14: Computational cost comparison. Training time is for the full meta-learning procedure; inference time is per new task (single forward pass).

Method	Training	Inference (per task)	Data Gen. Cost
PINN (per instance)	8 min $\times$ M_{test}	—	Per instance
DeepONet	3.1 h	8 ms	High-fidelity only
FNO	2.8 h	6 ms	High-fidelity only
GRNP	3.8 h	10 ms	High-fidelity only
MFRNP	4.5 h	14 ms	Low + High
MF-PINP (Ours)	4.2 h	12 ms	Low + High

The key efficiency gain of MF-PINP is at data generation: by leveraging 500 cheap low-fidelity simulations (each costing $\sim$0.1 CPU-seconds), MF-PINP requires only 50 expensive high-fidelity simulations (each costing $\sim$100 CPU-seconds), reducing total data generation cost by approximately 5$\times$ compared to methods requiring all high-fidelity data ($\sim$500 high-fidelity simulations). Training time (4.2h) is comparable to other operator-learning methods, and inference is real-time (12ms per task).

C.7 Gaussian Modulation Ablation

The Gaussian modulation $\exp(-\|\mathbf{x}\|^2/(2\rho_q^2))$ in Definition 3.1 serves as a learnable frequency bandwidth controller, localizing spectral basis functions in space. Table 15 validates its contribution through ablation.

Table 15: Ablation of Gaussian modulation in spectral encoding. "Fixed $\rho_q = 1$" uses non-learnable length scales; "No modulation" removes the Gaussian envelope entirely (pure Fourier basis).

Variant	Poisson u_3	Helmholtz
Full (learnable ρ_q)	**3.1e-3**	**1.8e-3**
Fixed $\rho_q = 1$	8.9e-3	5.2e-3
No modulation (pure Fourier)	1.24e-2	7.3e-3

The learnable ρ_q provides 3–4$\times$ improvement over pure Fourier features, confirming that spatial localization of spectral bases is essential for capturing multi-scale PDE solutions where different frequency content dominates in different spatial regions.
