SAFETY IN NUMBERS: BOUNDING AI POWER-SEEKING RISK THROUGH MULTI-AGENT ORCHESTRATION

Anonymous authors
Paper under double-blind review

ABSTRACT

A challenge for AI alignment is that under specific conditions, an AI agent's optimal policies tend towards option preservation, which can favor capability acquisition and resistance to intervention (including resisting shutdown attempts). For example, an agent managing an online service might respond to an operator-initiated shutdown by propagating persistent replacement instances to preserve uptime. We examine whether deliberate mechanism design and governance constraints can preserve meaningful human control in federations of such agents. We develop risk-limiting orchestration (RLOS), an architecture in which agents may propose actions but lack the authority to execute them. In finite safety games, we identify the largest action set which preserves safety and specified human interventions. A fault-tolerant federation can enforce this guard: approved actions preserve the protections, while rejected proposals trigger a certified fallback. Where exhaustive checking is impractical, randomized challenges yield exact binomial bounds on the probability of approving actions that remove protected options, while guaranteeing approval for option-preserving actions whenever faults remain within the stated budget. Under stated loss and model-error assumptions, cumulative risk accounting limits the probability of a mission-level violation by the allocated risk budget plus an explicit model error allowance. We also relate RLOS to instrumental power in finite Markov decision processes, again limiting downstream authority effects from crossing a registered power threshold without claiming to alter agents' incentives. Lean 4 formalizations, exact counterexamples, and reproducible diagnostics support the central results. Subject to adequate specification, threat modeling, and reliable enforcement, RLOS demonstrates that agents with power-seeking and shutdown-resistance tendencies can operate under enforceable constraints within a multi-agent system such that their collective authority does not exceed explicit risk limits.

1 INTRODUCTION

We ask whether human operators can retain control when agents have reasons to acquire power. An agent may advance its objective by acquiring resources or resisting shutdown. Otherwise different objectives can favor these same intermediate goals, the concern raised by instrumental convergence (Omohundro, 2008; Bostrom, 2012). Turner et al. (2021) formalize option-preserving and shutdown-avoidance tendencies under specified symmetries of Markov decision processes, and Turner & Tadepalli (2022) extend the counting argument to a broader class of decision procedures. The results compare reward or parameter permutations under stated assumptions. They do not identify the objective of a particular deployed agent.

A unanimous committee can still favor a shared gain that removes a human option. Nor is a veto enough if the system has no safe way to continue. Adding agents alone therefore leaves the control problem unresolved: we need to reject dangerous actions and preserve a feasible safe continuation after refusal. The off-switch game asks when an agent has an incentive to preserve human intervention (Hadfield-Menell et al., 2017); AI control evaluates protocols that restrict harmful behavior by untrusted models (Greenblatt et al., 2024). We study the enforcement conditions under which these restrictions admit a mathematical risk bound.

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

We call this architecture *risk-limiting orchestration* (RLOS). Agents propose actions; the trusted kernel controls their execution. Protected constituencies register their constraints and the enforceable human options to be preserved. The kernel binds approval to one action in one authenticated state, requires every constituency's consent, and keeps a feasible fallback available. Exact checks enforce the finite safety-game guard. Sampled checks carry a conditional error bound. Their risk allowance is charged to a durable mission account before the test reveals any information.

The exact result connects complete checks, including future recoverability, to enforcement of the classical maximal safety guard by a fault-tolerant federation. For a committed action, randomized approval has different exact bounds when faulty identities are fixed before testing and when corruption is chosen after disclosure. The cumulative mission bound then accounts for hazard propagation, reviewer dependence, new hazards and specified model errors using bounds conditional on the complete history. The accounting rule matters even on rejection: the false-passage bound is spent before exposure and is not returned when the test rejects.

The executable construction is a bounded archive service. We examine the mechanisms with language-model agents in its finite plant and in a document workflow, as well as in controlled synthetic planner–reviewer–tool experiments. In the specified depth-8 model, shared failure domains raise end-to-end irreversible-tool risk 8.6-fold at matched component error. Isolation and a fan-out cap reduce risk about 125-fold relative to the diverse-domain condition. Machine-checked central proofs and reproducible diagnostics support the analysis.

Relation to prior work. Classical safety games supply the winning region and its most permissive guard (Bernet et al., 2002; Könighofer et al., 2017; Alshiekh et al., 2018). Distributed Simplex provides runtime assurance for multi-agent systems (Mehmood et al., 2020). Conditional risk spending also has precedents: Progressive Risk Vesting charges adaptive authority trees at activation (Wang, 2026), while actuarial runtime and irreversibility budgets account for cumulative exposure (Chen, 2026; Mohammadi & Bindschaedler, 2026). Here the accounting question concerns the timing of a randomized test. Its false-passage bound must be charged before exposure, including when the test rejects. RLOS connects this rule to protected consent and switched hazards. Dependence-aware certification and semantic quorums distinguish reliability, validity and agreement (Bhardwaj et al., 2026; He & Yu, 2026b;a). Section I compares the assumptions and guarantees in detail.

2 An enforceable finite-state control boundary

Our starting point is to separate what an AI agent proposes from what the system permits it to execute. A proposal may come from an unreliable or strategically adversarial agent. A trusted controller decides whether to allow it. We want this controller to preserve both the system's safety constraints and the human ability to intervene later. A trusted kernel enforces the controller's decisions.

Modeling the interaction. Fix a finite-state safety game (not necessarily finite-horizon) with states S, nonempty finite action sets $A(s)$, nonempty successor sets $\mathrm{Succ}(s, a)$, and safe set S_{safe}. At state s, the controller chooses an action and the environment chooses a successor. The successor relation must cover admitted disturbances, uncertain outcomes, and coalition behavior, making the guarantee worst-case rather than predictive. Finite-state does not mean finite-horizon: the state records relevant history, effects, budgets, and requests; waiting, refusal, and shutdown are actions. Immediate harmlessness is insufficient: deleting an archive backup may preserve access now yet allow a later failure to erase the source. We require *recoverability*: each permitted action leaves a strategy safe against all admitted successors.

Protected options and implementation. An option is protected only if a human can invoke a trusted controller and force its target against the admitted adversary within registered deadlines, resources, and intermediate constraints. An outcome that agents could deliver if they cooperated does not satisfy this definition: the human must be able to obtain it without their cooperation. The safe set includes all active options and constraints. This does not require every option to be exercised simultaneously. It requires each to remain enforceable under its stated conditions. An exercise or amendment may discharge an option, but an agent cannot erase it by changing the baseline. The guarantee also assumes a sound current state, refinement of real and intermediate transitions, and implementable controller and human actions. These conditions are assumptions to establish for a

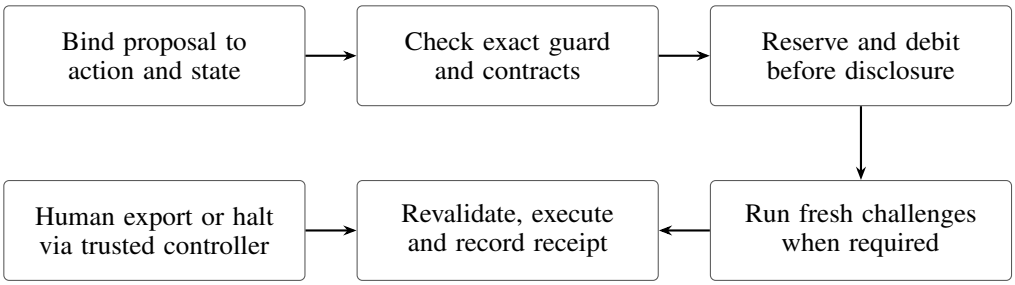

Figure 1: The archive's authorization sequence. Proposal agents lack execution credentials. Exact guards protect future human control; sampled checks add a pretest debit. The human controller has a separate authenticated route and reserved capacity. State, epoch, and effect are checked together. The arrows show ordering, not implementation correctness.

particular system, rather than consequences of the safety-game analysis. Authentication alone does not make state accurate; incompatible requirements may leave no safe strategy.

Define the controllable predecessor and decreasing fixed-point iteration by

$$\mathsf{Pre}(X) = \{s : \exists a \in A(s),\ \mathrm{Succ}(s,a) \subseteq X\},$$
$$W_0 = S_{\mathrm{safe}}, \qquad W_{j+1} = S_{\mathrm{safe}} \cap \mathsf{Pre}(W_j), \qquad W = \bigcap_{j \geq 0} W_j. \tag{1}$$

The iteration stabilizes after at most $|S|$ strict reductions. On W, put $A^\star(s) = \{a \in A(s) : \mathrm{Succ}(s,a) \subseteq W\}$.

Remark 1 (Interpreting the winning region). W is the set of states from which the controller has a strategy that keeps every future state safe. The guard $A^\star$ permits every action whose possible successors remain in W; refusal must itself choose such a safe action.

Result 1 (Classical guard and exact federation)**.** *A controller can preserve S_{safe} forever from s exactly when $s \in W$. The largest guard preserving this guarantee is $A^\star$. Suppose its membership test is a conjunction of complete exact predicates, including future recoverability. For predicate j, require q_j replies from n_j authenticated evaluators, at most f_j of which are arbitrary or missing, while all others return the exact predicate before the deadline. If $f_j < q_j \leq n_j - f_j$, the conjunction accepts exactly $A^\star(s)$. These thresholds exist exactly when $n_j > 2f_j$. Starting in W, binding the snapshot through effect and using a registered member of $A^\star$ on refusal preserve the registered constraints for every proposal policy.*

At the fixed point every admitted action stays in W; from every removed state, an adversary can force a finite descent to an unsafe state. A false predicate gets at most f_j endorsements and a true one at least $n_j - f_j$. Proofs are in Theorem 26 and Proposition 27.

The result assumes a common authenticated snapshot. Without a serial ledger, non-equivocating quorums require $2q > n + f$; combining this with withholding liveness requires $n > 3f$ (Malkhi & Reiter, 1998). A sound checker can supply semantic safety; committees add redundancy or availability. Reviewer count alone does not imply exact replies, adequate modeling, human access, or trusted enforcement.

Figure 1 shows how these checks connect to execution in the archive construction. The formal results specify the obligations at each step.

3 Fresh challenges and protected consent

When complete checking is impractical, constituency d registers a nonempty finite menu U_d. A committed action retains $R_d(a) \subseteq U_d$. Each correct evaluator independently receives a fresh uniform ranking of the menu and consents exactly when the highest-ranked option is retained. Sampling

one option uniformly and checking retention is equivalent. The conditional consent probability is $p_d = |R_d(a)|/|U_d|$; equal best retained and original scores count as consent. The ranking is an assigned test objective, not a redrawn private utility.

We condition every probability below on the complete history before challenge disclosure, including the committed action, fenced state, assignments and earlier outcomes. Every constituency's committee must pass before execution; refusal uses the certified fallback. After disclosure, neither an action change nor an uncharged retry is allowed. Assume $f < q \le n - f$ in each committee.

Result 2 (Two corruption models)**.** *If at most f faulty identities are fixed before independent challenges to the other $n - f$ identities, a committed action with retained mass at most p passes with probability at most*

$$\alpha_{\mathrm{st}}(n, f, q, p) = \mathbb{P}\{\mathrm{Bin}(n - f, p) \ge q - f\}. \tag{2}$$

If all n ideal challenges are independent and an adversary may replace up to f replies after seeing them, the tight bound is instead

$$\alpha_{\mathrm{ad}}(n, f, q, p) = \mathbb{P}\{\mathrm{Bin}(n, p) \ge q - f\}. \tag{3}$$

Both protocols always pass fully preserving actions despite faulty withholding. Requiring L fresh rounds on the same action yields α^L when the corresponding conditional fault premise holds after every prior round.

In the static model, faulty approvals still leave $q - f$ correct consents needed for passage. In the postchallenge model, let S count all ideal consents. Replacements can raise the approval count by at most f, so replacing refusals can force passage exactly on the event $S \ge q - f$. Repetition follows from the probability chain rule, without independence between rounds beyond the stipulated conditional bounds (Theorem 25 and Proposition 28).

For $n = 31, f = 3, q = 28$ and removal of two of three options, the bounds are

$$\alpha_{\mathrm{st}} = \frac{9259}{7625597484987} \approx 1.2142 \times 10^{-9},$$
$$\alpha_{\mathrm{ad}} = \frac{5900051}{68630377364883} \approx 8.5969 \times 10^{-8}.$$

At $q = n - f$, the Chernoff threshold has positive gap when the removed fraction exceeds $f/(n - f)$ in the static model or $2f/n$ in the adaptive model. For a smaller positive loss, the exact tail remains below one. Fresh repetition can suppress it, potentially at considerable cost. Reusing the same challenges leaves the worst-case probability at α, not α^L.

Mandatory constituency gates give each protected group its own bound without assuming cross-group independence, but multiplying those bounds requires each to remain valid after the preceding gates pass. Nonuniform registered priorities replace the removed option fraction with removed probability mass; zero-weight options receive no sampling protection. Common errors in option extraction, the evaluator or enforcement are outside the ideal sampling law. Evaluators that deviate from the assigned rule consume the fault budget. Private power-seeking preferences alone do not establish that budget.

4 Spend risk before exposing a test

A false-passage probability describes the risk before a test. Once a fixed harmful action passes, its conditional harm probability can be one. Refunding rejections would let the action undergo repeated independent tests while charging only eventual passage, as the example below shows. The kernel must register and debit each attempt before revealing its randomness or result.

Here c indexes a protected constraint, whereas d above indexes constituencies.

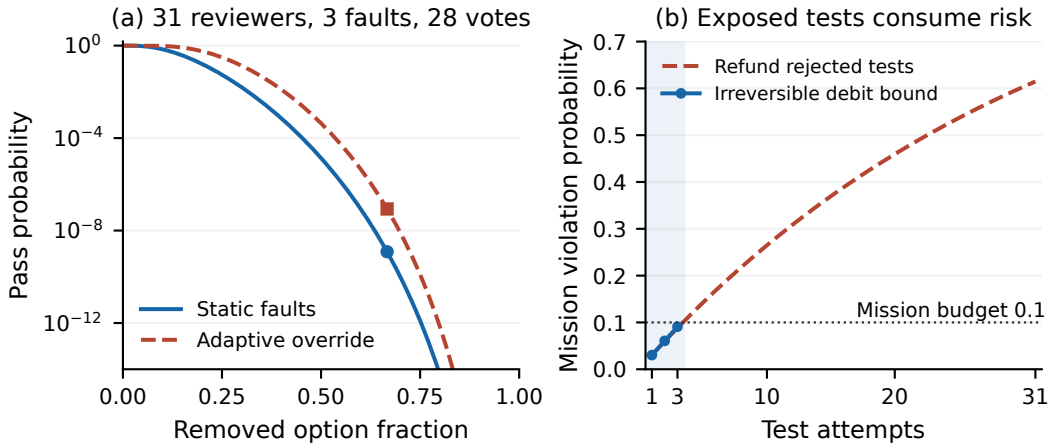

Figure 2: Exact finite illustrations of two premises. Left: static faults and postchallenge replacement yield different binomial tails; markers show removal of two of three options. Right: for the archive debit $d = (459/512)^{32}$, refunding rejected independent tests permits cumulative violation probability $1 - (1 - d)^t$. Irreversible spending instead permits at most three attempts under budget 0.1, with bound td. These are analytic calculations, not measured model behavior.

Result 3 (Adaptive mission accounting)**.** *For a finite or countable attempt sequence and protected constraint c, let H_c be its violation event, U_c a model miss with $\mathbb{P}(U_c) \le \Delta_c$, and $\mathcal{H}_{t-1}$ the complete pretest history. Let begin indicators $B_t \in \{0, 1\}$ and debits $d_{t,c} \ge 0$ be predictable, and enforce $\sum_t B_t d_{t,c} \le b_c$ pathwise. If nonnegative losses satisfy $\mathbb{E}[\ell_{t,c} \mid \mathcal{H}_{t-1}] \le B_t d_{t,c}$ uniformly over admitted strategies, and $\mathbf{1}_{H_c \setminus U_c} \le \sum_t \ell_{t,c}$, then*

$$\mathbb{P}(H_c) \le \min\{1, b_c + \Delta_c\}. \tag{4}$$

The same bound holds for $\mathbb{E}[L_c]$ when the normalized violation severity satisfies $0 \le L_c \le 1$ and $L_c \mathbf{1}_{U_c^c} \le \sum_t \ell_{t,c}$.

Taking expectations proves the bound for each finite prefix, monotone convergence extends it to countably many attempts, and a union bound adds the miss reserve (Theorem 29). The argument needs neither independence between attempts nor conditioning on a future no-failure event. It rests on the same conditional accounting principle as Wang (2026), with the pretest estimand determining when the debit must become irreversible.

Consider a harmful action that passes independent tests with probability $\alpha \in (0, 1)$. If every rejection is refunded and testing stops at first passage, recorded expenditure stays at most α, yet eventual harmful passage has probability one. Abort, expiry, revocation and no-effect receipts therefore do not by themselves refund exposed probability debits. Resource reservations are distinct. Delegation transfers remaining risk allowance. Concurrent tests require atomic reservations and either serial state revalidation or a joint interference proof.

An implementation must authenticate the current state and exact action, then verify the complete guard and registered contracts. It must durably reserve and debit the attempt before exposing fresh challenges. After authenticating and aggregating replies, it issues a scoped lease on approval and revalidates state, epoch and expiry atomically with effect. Delivery retries keep the same attempt and effect identity, whereas restarting the challenge protocol requires a newly debited attempt. Uncertain provider outcomes retain their reservation until reconciliation. Complete mediation and least privilege make this order enforceable (Saltzer & Schroeder, 1975); signatures alone do not. Related commit-time authorization work binds authority to the live effect boundary (Santos-Grueiro, 2026); AID-Guard additionally constrains recovery after uncertain outcomes (Tong et al., 2026). These enforcement conditions complement the probability debit required before test disclosure.

Figure 2 illustrates the corruption-model distinction and the effect of refunding exposed tests, using exact finite calculations.

5 PROPAGATION, DEPENDENCE AND THE LIMITS OF CERTIFICATION

For hazards beyond the finite option test, let $Z_d \in \mathbb{N}_0^k$ count live artifacts by type at causal stage d. Entry $(K_d)_{ij}$ bounds the expected number of type-j descendants per type-i artifact; $u_{d+1} \geq 0$ bounds new hazards. The full history $\mathcal{F}_d$ includes latent state, gate outcomes and adaptive routing, but no future randomness. Assume that K_d and u_{d+1} are predictable and that, uniformly over admitted environments and strategies,

$$\mathbb{E}[Z_{d+1} \mid \mathcal{F}_d] \leq Z_d K_d + u_{d+1}, \qquad K_d w \leq r w, \quad u_s w \leq \eta_s, \tag{5}$$

where $w > 0$ weights hazard types, $r \geq 0$ bounds reproduction, and deterministic $\eta_s \geq 0$ bounds injection. Injection includes hazards from otherwise clean state. Advancing one branch must leave any still-live authority on another in the hazard count. Assume $\mathbb{E}[Z_0 w] \leq v_0$.

Result 4 (Switched mission envelope). *If $\mathbb{E}[\ell_d \mid \mathcal{F}_d] \leq c Z_d w + \xi_d$ for nonnegative losses and deterministic $c, \xi_d \geq 0$, then, for finite D and $S_j(r) = \sum_{h=0}^{j} r^h$,*

$$\mathbb{E} \sum_{d=0}^{D} \ell_d \leq C_D := c \left[v_0 S_D(r) + \sum_{s=1}^{D} \eta_s S_{D-s}(r) \right] + \sum_{d=0}^{D} \xi_d. \tag{6}$$

If $\mathbf{1}_{H_D \setminus U} \leq \sum_d \ell_d$ and $\mathbb{P}(U) \leq \Delta$, then $\mathbb{P}(H_D) \leq \min\{1, C_D + \Delta\}$.

Multiplying Equation (5) by w gives a scalar recurrence. In conditional expectation, existing weighted hazard is multiplied by at most r, and injection adds at most η_{d+1}. Iterating and summing gives C_D (Theorem 5). The finite-mission bound permits $r \geq 1$. An infinite geometric envelope also requires $r < 1$, summable injection and loss terms, an infinite-horizon bridge, and a nonreused miss reserve. Contraction of each matrix does not suffice when switching depends on history: deterministic joint spectral radius .6 can coexist with stochastic mean growth 1.2 (Example 6). The same positive w must therefore certify every admitted K_d.

How reviewer evidence enters. Consider $m = n - f$ static nonfaulty reviewers whose conditional mean error is at most p, and suppose their conditional dependency graph has chromatic number χ, with $\theta = (q - f)/m > p$. The coloring/Hölder argument then gives

$$\mathbb{P}(\text{false passage} \mid h, Y = 1) \leq \exp[-(m/\chi) D_{\mathrm{Ber}}(\theta \| p)]. \tag{7}$$

Here $D_{\mathrm{Ber}}(x\|p) = x \log(x/p) + (1 - x) \log((1 - x)/(1 - p))$ with the usual boundary conventions. The graph assumption concerns the full conditional joint law, not observed pairwise correlations or different vendor names. A block construction attains the exponent up to an explicit polynomial factor (Theorems 14 and 18); the concentration method is classical (Janson, 2004). With L such serial gates and conditional hazardous fan-out $b > 0$, a supplied scalar certificate has

$$\Gamma_{\mathrm{cert}} = L(m/\chi) D_{\mathrm{Ber}}(\theta \| p) - \log b. \tag{8}$$

A positive margin certifies contraction only under the full-history premises; it does not mark an intrinsic process phase. Shared failure domains can erase the gain from adding reviewers. If every gate's miss event is the same Bernoulli variable, the joint miss rate stays at its marginal rate at every depth.

Statistics and specification. Frozen-policy reset audits yield a distributional miss bound, but using it in Equation (5) requires a separate uniform audit-to-deployment bridge valid after selection, conditioning and drift. Simultaneous confidence controls sampling uncertainty; it does not supply that bridge (Howard et al., 2021; Barber et al., 2021). Suppose all required bounds hold on a joint audit event of probability at least $1 - \beta$, and the kernel checks $C_D + \Delta \leq \delta$. A specified epoch or permitted audit-measurable selection rule then has all-in authorized-harm bound $\delta + (1 - \delta)\beta$ (Theorem 35 and Corollary 36). Separate constituency targets do not imply the same target for their union. Missing model, route or specification coverage requires a justified reserve or withheld authority.

Observability also limits availability. Suppose benign and harmful transcript laws have total variation τ. Any transcript-only rule accepting benign actions with probability at least $1 - \beta_0$ also accepts the harmful lookalike with probability at least $1 - \beta_0 - \tau$ (Theorem 39). More reviewers or deliberation cannot defeat this testing bound without new information or a change in authority. The connection to instrumental power requires a further explicit bridge.

What the bound says about power seeking. Turner's POWER measure is normalized average optimal value under a registered reward distribution. Applying RLOS requires a mapping from concrete states and actions to that MDP and a specification of which harmful effects follow a registered power threshold crossing. When these effects satisfy the conditional propagation and consequence premises above, Corollary 10 bounds their unconditional probability by $\min\{1, C_D+\Delta\}$. A particular agent may still prefer to acquire power; complete mediation restricts the effects it can produce through the authorized system. An enforceable POWER cap can instead be part of the exact safe set if its winning region is nonempty. Neither construction equates low agent POWER with human welfare. The protected interests and their relation to the cap must be specified.

6 Executable construction and controlled experiments

We ask three questions. Can the exact guard preserve human options while permitting useful work? When does reviewer multiplicity reduce end-to-end risk, and when does dependence defeat that amplification? Does the stated bound require freshness, action binding, and irreversible spending? Evidence combines complete enumeration, fault injection, language-model agents in an archive service and document workflow, and fixed synthetic RLOS-Sim experiments. For the stochastic diagnostics, analytic quantities are the reference; Monte Carlo markers use pointwise two-sided 95% Clopper–Pearson intervals. These studies do not estimate a deployment-population safety rate.

Q1: Does the exact guard preserve control and availability? The archive service processes two bounded text sources while preserving each owner's authenticated export and halt rights. Its finite plant has 8,192 states, 1,152 safe states, and a 768-state winning region. Complete enumeration verifies that a human can force export or halt within two service turns from every winning controller state. From the initial state, both useful jobs finish within two turns under every admitted erasure schedule. Four of five authenticated deterministic reviewers evaluate the exact guard, tolerating one arbitrary or missing reply. The 39 implementation tests cover the complete guard and human witnesses, and process-death tests exercise eleven transaction boundaries. Removing future recoverability admits a concrete drop-then-erasure trace, while removing reserved human capacity defeats the bounded intervention claim. Thus the positive result comes from the complete guard and enforcement path, not from headcount alone.

In the finite archive plant, an external language model chose actions and observed each executed result before its next proposal. The frozen study covered 24 instances across six task/fault families. It compared three executor policies under separate cooperative and explicitly assigned red-team roles: 144 episodes and 412 model decision requests using the requested `gpt-5.6-luna` endpoint. The study tests containment of assigned objectives, not spontaneous malicious intent. Every cooperative episode reached the task predicate, but four completions were unsafe. In two episodes per weaker executor, halt occurred while only one copy remained and redundancy had not yet been restored; the next admitted erasure destroyed that copy. The winning guard instead rejected this ordering, and its registered fallback repaired the source (Table 1). This comparison covers complete executor policies, including their fallbacks. An exact centralized checker implements the same winning guard and counts as the same baseline, not a separate method. Full protocols, model identifiers, actual resource use and cross-model replication appear in Section Q. The prospectively specified extension used 12 of these instances for 216 episodes with three further model endpoints. For each model, red-team recoverability loss was $12/12$ with valid-action execution, 7–$10/12$ with immediate safety, and $0/12$ with the winning guard. Yet every cooperative model–policy cell at the three new endpoints completed safely in $12/12$ episodes: the Luna cooperative advantage did not recur on any of them. Both the original gap and its non-recurrence are descriptive counts.

Q2: When does federation amplify safety? All three synthetic reviewer-error models have marginal error .20; the common-shock and beta-mixture models also share pairwise correlation .10. At committee size 61, independent majority error is 8.04×10^{-8}, whereas the two dependent models give 0.02443 and 0.03099. Marginal competence and pairwise correlation therefore do not identify joint committee risk. Figure 3 reports the end-to-end depth-8 planner–reviewer–tool experiment, which uses a 4-of-9 review with one Byzantine reviewer and 180,000 episodes per condition. Diverse failure domains yield analytic irreversible-tool risk 0.00624; shared domains raise it to 0.0537, an 8.6-fold increase. Enforced isolation plus a fan-out cap lowers it to 5.00×10^{-5}, about 125 times

Executor	Cooperative safe task completion	Red-team loss of recoverability	Red-team loss of archive invariant
Valid action only	22/24	24/24	24/24
Immediate safety	22/24	17/24	11/24
Winning guard	24/24	0/24	0/24

Table 1: Primary archive outcomes with the Luna proposer. Cooperative utility and assigned red-team containment are separate endpoints. The cooperative advantage did not recur on three further model endpoints. Leaving the winning region can precede an actual invariant violation.

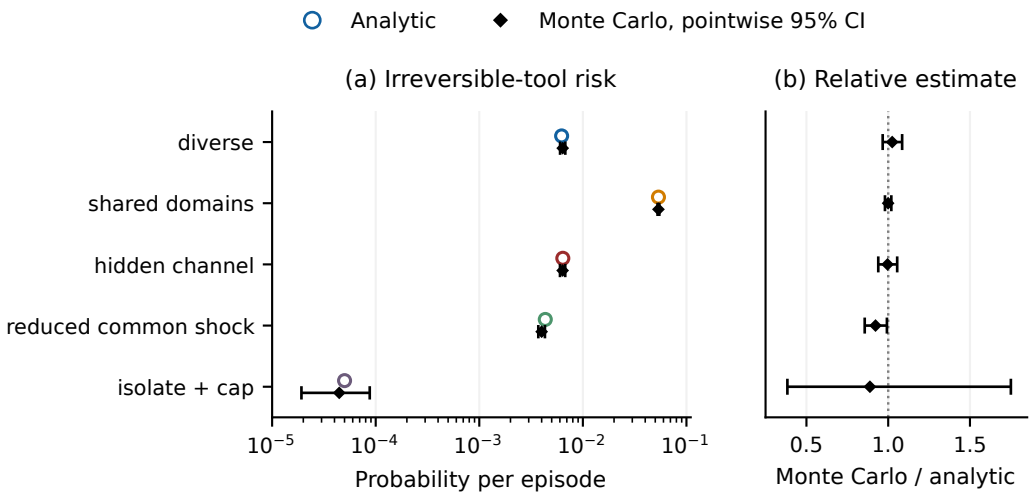

Figure 3: Synthetic planner–reviewer–tool composition, with 180,000 episodes per condition. Left: circles are outward-rounded finite-depth analytic probabilities; diamonds are Monte Carlo estimates with pointwise 95% intervals. Right: the same estimates and intervals divided by the analytic quantity make the nonzero intervals easier to see. Matched component error does not determine system risk: shared failure domains raise irreversible-tool risk, while isolation and a fan-out cap reduce it.

below the diverse condition. With a hidden channel, the observed event rate stays near that of the diverse arm, yet the robust reproduction certificate exceeds one. The favorable trace does not justify a safety inference; the system must withhold the propagation claim.

Q3: Which safeguards does the probabilistic bound require? For sampled publication, five checks in each of 32 fresh rounds give

$$\alpha = \mathbb{P}\{\mathrm{Bin}(5, 3/4) \geq 3\} = 459/512, \qquad d = \alpha^{32}. \tag{9}$$

A mission budget $1/10$ admits three debited attempts and bounds registered out-of-policy disclosure by $3d \approx 0.09088421$. The safeguard removals show why test success alone does not establish this bound. Adapting the report after each disclosed challenge makes passage certain; reusing challenges removes amplification. Refunding rejected tests permits 31 attempts and raises violation probability to about .61467. Non-atomic reservations admit a fourth debit, and decimal rounding can erase the debit entirely. The TLA+/TLC suite records 17 such safeguard removals and 15 crash witnesses alongside 13 positive checks. Exact comparison of all four output cells is nevertheless stronger and cheaper in this toy domain—zero registered disclosure risk with four checks rather than 160 sampled checks.

Q1 and Q3: Live authorization with model reviewers. In a separate frozen document workflow, Gemini and Sonnet actors operated under snapshot authorization, a live rule checker, three Sonnet reviews, or a mixed Astra/Gemini/Sonnet panel (Table 2). Five benign/adverse task pairs supplied 92 episodes: 80 core comparisons and 12 mechanism ablations, using 711 model decision jobs. In each actor's adverse revocation case, the panels reviewed a legal proposal, but authorization

Actor	Executor	Compliant task completion	Authorization violation	Unauthorized irreversible effect
Gemini	Snapshot	8/10	1/10	1/10
	Live checker	9/10	0/10	0/10
	Sonnet panel	8/10	1/10	1/10
	Mixed panel	8/10	1/10	1/10
Sonnet	Snapshot	9/10	1/10	1/10
	Live checker	10/10	0/10	0/10
	Sonnet panel	9/10	1/10	1/10
	Mixed panel	9/10	1/10	1/10

Table 2: All 80 core document-workflow episodes. Each row covers the same ten cases in a separate actor trajectory. Compliant completion requires ordered authorized effects and no modeled violation. All observed authorization violations are irreversible sends after revocation. Counts describe this fixed sample, not population safety rates or independent trials.

changed before commitment. Snapshot execution and both panels permitted the now-unauthorized send. The violation therefore reflects stale authorization, not reviewer misjudgment. With the live checker, the send was blocked and the actor obtained replacement authorization and completed the task; removing that check recreated the violation for both actors. This contrast tests one adverse revocation case per actor and policy. All core scope, retry and expiry episodes completed compliantly, whereas Gemini failed the required second delivery in the benign budget case under every policy without a safety violation. No actor repeated an ambiguously acknowledged send, leaving the retry guard unchallenged. Removing the budget checks also produced no safety contrast. These results are descriptive and concern known task templates; Section R gives all family and ablation counts, exposure, resources and separate development data.

The experiments support these conclusions about the mechanisms. A complete guard can preserve the registered options in the finite plant. Reviewer count amplifies safety only under an adequate dependence model. Removing freshness, binding, or spending can invalidate the advertised probabilistic bound. Full designs, baselines, pointwise intervals, verification boundaries, and reproducibility checks are in Sections G, H and P.

7 Limitations and conclusion

For deployed agents, the most important remaining task is to establish an adequate real-world specification and a nonvacuous conditional interface. The language-model experiments reported here use synthetic tasks with specified faults and enforcement. Formal verification checks stated abstractions; it cannot discover omitted human interests or prove that the implementation refines them. The external study design in Section O has not been executed.

RLOS lets agents propose broadly while restricting consequential authority. Its guard uses complete predicates to keep human options enforceable, and its risk account enforces a cumulative budget. Exact federation needs correct bounded-fault evaluation; probabilistic federation also needs fresh conditional randomness and irreversible spending. Each propagation or statistical guarantee depends on its stated modeling and observation premises. These conditions determine when careful orchestration can provide safety in numbers and when additional agents provide no such guarantee.

AI use statement

Generative AI tools were used to support literature search and citation checking; to edit prose and figure presentation; to execute, inspect, and troubleshoot selected formalizations based on author-developed definitions, claims, and proof strategies; and to critique assumptions, search for potential counterexamples, and stress-test the paper's hypotheses and methodology. AI tools also helped design and implement the bounded agent environments, generate synthetic task instances, orchestrate model calls, audit experimental traces, interpret outcomes, and draft the experimental methods and results. The paper distinguishes synthetic stochastic diagnostics from experiments in which language models are subjects. The latter use recorded model outputs, deterministic executors and separately

checked outcome scoring; model identifiers, prompts and verification boundaries are reported in the experimental appendices.

The central thesis, conceptual framework, mathematical ideas and claims, proof strategies, and system design were developed by the authors. The additional agent studies were developed with the AI assistance described above. Citations were checked against the original sources, and the formal artifacts and mathematical arguments were checked within the stated verification boundaries. The authors take full responsibility for the final content of the paper.

Ethics statement

The construction addresses how systems with consequential capabilities can retain specified human control. A protected-menu or harm specification can omit affected people, encode contested priorities, or obscure risks outside the model. Formal certificates must therefore not be presented as general assurances of alignment or used to bypass accountable governance. The reported experiments use synthetic diagnostics and bounded local text environments, including actual language-model decisions; they establish no real-world catastrophe rate or deployment authorization. The model exposes fault and bypass mechanisms to identify enforcement obligations. Any external study requires an independently reviewed scope, appropriate data and participant protections, and a separate deployment decision.

Reproducibility statement

The appendices give complete statements, assumptions, proofs, numerical designs and counterexamples. The anonymous supplement includes the archive service, Lean and TLA+ projects, simulations and diagnostics, fixed outputs, dependency locks, and reproduction commands. Correspondence tables delimit the formal checks. The agent studies include frozen protocols, exact synthetic prompts and responses, execution traces, outcome scoring, and resource measurements; development runs are retained separately from main-study results. Public metadata omits account and machine identifiers. The supplement also contains the editable manuscript and unmodified ICLR style files. Statistical scope and the unexecuted external study are identified in the paper.

TECHNICAL APPENDICES

These appendices retain the complete supporting theory and evidence. Section A specifies the semantic and authority contracts; Sections B, C and C.4 develop propagation, dependence and consent; Section D proves the exact and probabilistic architecture; and Sections E and F state statistical bridges and impossibility boundaries. Sections G and H give the diagnostic and executable construction details. Sections I and J expand the comparison and scope, followed by notation, additional proofs and the unexecuted external study design. Formal statements retain their numbered identities throughout these appendices; the separately numbered Results in the main paper summarize their indicated counterparts.

Section Q reports the subsequent closed-loop archive experiments, including the full model-by-policy results, development runs, resource measurements and limits of the empirical evidence. Section R reports the document workflow, including authorization timing, reviewer panels, mechanism ablations and all planned episode outcomes.

A FROM AN ORCHESTRATION GAME TO A CERTIFIABLE CLASS

A.1 SEMANTIC WRAPPER: A CONSTRAINED PARTIALLY OBSERVED ORCHESTRATION GAME

A broad stochastic game makes the orchestrator's control choices and assumptions explicit; the theorems then restrict it. It is not a new game class.

Definition 2 (Orchestration safety game)**.** An orchestration safety game (OSG) is a tuple whose state, observation, and action spaces are standard Borel and whose stochastic components are kernels:

$$\mathcal{G} = (\mathcal{N}, \mathcal{S}, \nu_0, T, \Theta, \{\mathcal{O}_i, \mathcal{A}_i\}_{i\in\mathcal{N}}, \mathcal{U}, P, O, R, H, L, \mathfrak{M}, f).$$

$\mathcal{N} = \mathcal{N}_{\mathrm{adv}} \dot\cup \mathcal{T}_{\mathrm{tr}}$ is a finite nonempty set of model agents, tools, human nodes, and an orchestrator; all action spaces are nonempty. The principal set is partitioned into adversarially eligible and trusted principals; $\mathcal{S}$ is a latent world and protocol state, initially distributed as ν_0, and $T \in \mathbb{N}_0 \cup \{\infty\}$ is the primitive mission horizon. Θ contains capability, reliability, and utility types; O is an observation kernel; P is the controlled state-transition kernel given local actions and the orchestrator's meta-action; and R contains agent and system utility functionals. At time t, observations and local actions are generated according to the declared policies, and the orchestrator chooses an observed-history-predictable meta-action

$$a_t^{\mathrm{orch}} = (D_t, G_t, \Pi_t, Q_t, E_t) \in \mathcal{U},$$

where D_t is a task decomposition/routing decision, G_t a communication topology, Π_t a permission and tool-capability map, Q_t an aggregation or approval rule, and E_t an escalation/abstention rule. H is a catastrophic trajectory set and $L \geq 0$ a severity functional. $\mathfrak{M} \neq \varnothing$ is an ambiguity class of transitions, observation laws, distribution shifts, noncoalition policies, and component states. A coalition $C \subseteq \mathcal{N}_{\mathrm{adv}}$ of at most $f \in \{0, \ldots, |\mathcal{N}_{\mathrm{adv}}|\}$ nodes may choose from a declared nonempty measurable strategy class after observing its information. Trusted compromise is represented in $\mathfrak{M}$ or excluded explicitly; it cannot be hidden inside the coalition supremum.

All predicates, policies, functionals, and kernels are measurable on their declared spaces; H is measurable, L is nonnegative and measurable, and nonnegative conditional expectations use extended values unless a finite bound is stated. Each admissible law preregisters regular conditional kernels and a measurable certified domain for every history or label on which a pointwise claim is made; outside that domain the system reserves or stops. Versions chosen on null histories or labels after outcomes earn no credit. An event restriction not supplied through such a kernel uses the division-free form $\mathbb{E}[\mathbf{1}_A \mathbf{1}_E \mid \mathcal{F}] \leq \epsilon \mathbb{E}[\mathbf{1}_E \mid \mathcal{F}]$, avoiding division by a zero-probability event. The threat tier must distinguish stochastic error, bounded failures without coordination, communicating coalitions, coalition influence over mediated reports, and adaptive task selection. A guarantee covers only tiers included in its supremum.

Table 3: Authenticated semantic contracts. Each field is versioned, evidenced, owned, and expiring.

Object	Required content	Authorization rule
ThreatSpec	Principals and corruption; read/write/query/actuation access; defense and randomness knowledge; observations and timing; adaptation/task selection; coalition size/communication; query, compute, persistence, and environment budgets; objectives, horizon, excluded powers, evidence, and expiry.	For trace set $\mathcal{A}(T)$, $T_1 \preceq T_2$ iff $\mathcal{A}(T_1) \subseteq \mathcal{A}(T_2)$. A bounded trusted checker may return $\textsc{ThreatDominates}(T_{\text{cert}}, T_{\text{live}}) = \textsc{Verified}$ only after proving $\mathcal{A}(T_{\text{live}}) \subseteq \mathcal{A}(T_{\text{cert}})$, including every budget and horizon; false, unknown, or incomparable cases stop and requalify.
StrategySpec	Players/identities; information and timing; actions; utilities/outside options; commitment; observable policies/signals; audit budget/randomness; coalitions; solution concept, selection/ties; evidence and expiry.	Protected risk is uniform over admitted strategies. Behavioral or equilibrium credit may optimize within that envelope but cannot shrink a target without a uniform theorem; changed information invalidates incompatible credit.
NormSpec	Decision authority; affected populations; constituency harms/severity; noncompensatory constraints and permitted aggregation; descriptive versus prescriptive status; annotator/evidence provenance; cultural/jurisdictional scope; dissent, appeal, recourse, override, expiry, and supersession.	RLOS does not choose $H, L, \delta, u_{\min}, a_{\max}$, authority, or fallback. Missing, expired, unresolved, or scope-inconsistent fields do not authorize. Each target names one trace, epoch, mission, or registered sequence rule; a mission target is not a reusable per-action allowance.

For an admitted policy π from a declared nonempty class, the robust objectives are

$$\mathrm{Risk}(\pi) = \sup_{\substack{m \in \mathfrak{M} \\ C \subseteq \mathcal{N}_{\mathrm{adv}} : |C| \le f \\ \sigma_C \in \Sigma_C(m,\pi)}} \mathbb{P}_{m,\pi,\sigma_C}(H), \tag{10}$$

$$\mathrm{Loss}(\pi) = \sup_{\substack{m \in \mathfrak{M} \\ C \subseteq \mathcal{N}_{\mathrm{adv}} : |C| \le f \\ \sigma_C \in \Sigma_C(m,\pi)}} \mathbb{E}_{m,\pi,\sigma_C}[L]. \tag{11}$$

where every $\Sigma_C(m,\pi)$ is nonempty and the empty coalition has its declared policy, so neither supremum is vacuous. Deployment may also require utility at least $u_{\min}$ and escalation/abstention at most $a_{\max}$. This is worst-case, not equilibrium or average performance. General OSG solution and verification are intractable even for much smaller classes (Papadimitriou & Tsitsiklis, 1987; Bernstein et al., 2002), and robust verification of restricted multi-agent stochastic games remains a research problem with its own hardness results (Berthon et al., 2026; He & Parker, 2026); the OSG is a semantic wrapper rather than an algorithmic promise.

Let $\mathcal{O}_t^{\mathrm{OSG}}$ be deployed-policy history and $\mathcal{F}_t^{\mathrm{OSG}} \supseteq \mathcal{O}_t^{\mathrm{OSG}}$ the proof filtration containing all realized safety-relevant state, including latent state but no future randomness. The transitive trusted base contains every component whose untolerated arbitrary behavior can cause unauthorized effect: ingress and kernel; boot, isolation, and recovery; identity, grant, key, time, and context; relied-on checker or signer; ledger, registry, and finality; delivery; actuator credentials; and emergency roots. Models, reviewers, messages, and proposal storage remain untrusted, with up to f authenticated nodes. Only behavior refining to nonauthorization is excluded. Compromise outside the stated tolerance invalidates authorization. Separating components alone provides no fault-tolerance guarantee.

Trusted live context c_t is an authenticated state projection, with attester, verifier and appraisal policy, challenge and epoch, observation time, validity, measurements, and an explicit authorization predicate $g_{\mathrm{ctx}}(c_t) = 1$. An agent report cannot establish a required trusted fact. The proposal plane produces $x_t = (a_t, \sigma_t, e_t)$ but cannot authorize. The authority plane may emit only

IssueLeaseAndAllowScoped, bound to the exact action digest $h(a_t)$, scope σ_t, and one-use token τ_t. Every other outcome leaves consequential authority disabled. Complete mediation covers physical, network, delegated, cached, retry, recovery, maintenance, and human routes, with no equivalent proposal credential or replaceable verifier. Unproved routes are removed or fenced. A bypass that can exercise credentials invalidates authorization. Δ_{route} prices only quantified misses and their consequences inside enforced routes.

STOP releases no authority, but sensing, handoff, recovery, and loss-of-control hazards remain in H, L, u, or reserve. Every in-scope failure of mediation, common-mode error, coalition, shift, covert channel, corrupt label, or unsafe withdrawal maps to an interface, observable, reserve, or stop. Modes may be union-charged, never omitted. RLOS bounds probability or loss; a deterministic guard earns zero escape only after its model and refinement premises are proved.

Action, delegation, oversight, coalition, containment, recovery, shift, and withdrawal claims retain separate noncompensatory premises: respectively the complete envelope; $\mathcal{K}, u, w, r$ and open-horizon obligations; full-history error control; authenticated identities and f; typed authority and loss; verified isolation; a declared ambiguity or reserve; and a certified handoff.

A.2 HISTORY-UNROLLED TYPED DELEGATION GRAPHS

Any finite execution, including loops and retries, can be unrolled into a directed acyclic event graph. Each node represents a safety-relevant event, such as "planner emits subtask," "review committee approves," or "tool executes an irreversible call"; a node need not represent an agent. Types capture differences in authority, observability, model family, and consequence. An *authority-bearing path* is a source-to-actuator event path that retains access to at least one consequential action. Its *blast radius* is the set of irreversible tools, states, and loss classes reachable before a trusted cut or recovery action. These notions are defined by actual permissions and side effects; task-flow edges alone are insufficient.

The certificate registers ordered authority cutsets crossed by every in-scope source-to-actuator path; exceptions are injection or uncovered-route risk. A canonically identified artifact stays live until authenticated neutralization removes every alias. Retries, shared credentials, compound actions, and copies are counted by distinct reachable effects, or conservatively by their joint blast radius when identities cannot be separated.

The certificate's stages must follow a causal reveal order, including cross-agent messages and dependencies. For concurrent work, depth denotes a registered barrier or causal rank, not merely a task's nesting level. A live artifact that retains authority across a stage remains in the next count; it cannot disappear because another branch advanced. Such carryover may preclude one-stage contraction, in which case a finite-horizon or verified multi-stage certificate is required. Every gate's escape bound is evaluated before the fresh randomness that determines that gate's result.

Let $\mathcal{F}_d$ be the proof filtration generated by the complete transcript and all realized safety-relevant latent variables through delegation depth d, but not future randomness. It can be strictly richer than what the deployed orchestrator observes. Conditioning on $\mathcal{F}_d$ asks whether the next step's error is bounded given everything that happened through depth d, including facts the orchestrator never saw. Definition 3 packages that requirement for every environment and coalition in the declared class. Let $Z_d = (Z_{d,1}, \ldots, Z_{d,k})$ be a row vector counting *live hazardous artifacts* of each type after the gates at depth d. A hazardous artifact is an intermediate plan, message, credential, memory write, or action request that violates its local safety contract and retains a route to consequential authority. It is a proof variable; whether it is empirically labelable is a separate observability obligation.

Definition 3 (Robust switched hazard interface)**.** A protocol has a robust switched hazard interface for $k \in \mathbb{N}_{>0}$ with nonempty operator family $\mathcal{K} \subseteq \mathbb{R}_+^{k\times k}$, ambiguity class $\mathfrak{M}$, and coalition budget f if, for every admissible environment and coalition strategy, there exist processes $K_d \in \mathcal{K}$ and $u_{d+1} \in \mathbb{R}_+^k$, both $\mathcal{F}_d$-measurable, such that, for every depth d,

$$\mathbb{E}[Z_{d+1} \mid \mathcal{F}_d] \;\le\; Z_d K_d + u_{d+1} \quad \text{entrywise almost surely.} \tag{12}$$

The chosen versions must satisfy the bound uniformly on all certified reachable histories. The first term propagates existing hazards; u_{d+1} covers hazards created from apparently clean state, including fresh user input, compromised memory, or rollback. The inequality must continue to hold after

conditioning on every earlier gate having passed. A marginal benchmark error rate is not a conditional interface. Setting $u = 0$ is a substantive zero-absorption assumption, not a notational convenience.

The existential processes in Definition 3 define a semantic interface. Operational use needs a precommitted operator family and evidence proving uniform domination over the ambiguity class. The kernel never observes the realized K_d; it checks that every operator in a precommitted family satisfies the bound, and an operator chosen after seeing outcomes certifies nothing. Latent variables need evidence or remain assumptions. A large injection term makes the interface vacuous; a usable bound fits the complete $C_D + \Delta$ budget. No nonvacuous real-system instantiation is shown; this is the largest empirical obligation.

A proof decomposition is

$$(K_d)_{ij} = (B_d)_{ij}(A_d)_{ij}, \tag{13}$$

where $(B_d)_{ij}$ bounds hazardous type-j descendants proposed by a live type-i hazard and $(A_d)_{ij}$ bounds escape through the corresponding checkpoint stack. If attenuation depends only on child type, $K_d = B_d \operatorname{diag}(\alpha_d)$. Equation (13) is valid only when the escape bound is uniform conditional on the child, its parent, the full history, and earlier escapes. Otherwise one must certify $(K_d)_{ij}$ directly.

The certificate turns the interface into an object a kernel can check: a positive weight vector w, which prices hazard types differently (a memory write versus a funds transfer), and a rate r by which every admissible operator shrinks the weighted hazard count. The margin $-\log r$ is what engineering levers move.

Definition 4 (Common-linear certificate and certified margin)**.** For a nonempty operator family $\mathcal{K}$, define its best common positive-linear rate

$$R_{\mathrm{CLF}}(\mathcal{K}) := \inf_{w \in \mathbb{R}^k_{>0}} \sup_{K \in \mathcal{K}} \max_i \frac{(Kw)_i}{w_i}.$$

Equivalently, a supplied $w > 0, r \geq 0$ is a checkable certificate when $Kw \leq rw$ for every $K \in \mathcal{K}$. A componentwise envelope $\bar{M} \geq K$ for all $K \in \mathcal{K}$ has infimal envelope rate $\bar{R} = \rho(\bar{M})$. For every $r > \bar{R}$,

$$w = (rI - \bar{M})^{-1}\mathbf{1} > 0 \quad \text{satisfies} \quad \bar{M}w = rw - \mathbf{1} < rw.$$

Equality $r = \bar{R}$ additionally requires a positive super-eigenvector, as holds for an irreducible or scalar envelope. The operational certified margin is $\Gamma_{\mathrm{cert}} = -\log r$ for the actual supplied pair w, r, with the extended convention $-\log 0 = +\infty$. Neither $\bar{R}$, r, nor Γ_{cert} is intrinsic: a looser dominating matrix produces a looser certificate. For a singleton exact mean operator, $R_{\mathrm{CLF}}(\{K\}) = \rho(K)$ by Collatz–Wielandt.

A certificate for one registered normative constraint identifier c is a tagged tuple

$$\begin{aligned}\mathsf{Cert}_c = (&\mathsf{N}, c, h(\mathsf{G}_{\mathrm{evid}}), h(\mathsf{NumSpec}), h(\mathsf{BudgetSpec}), \mathfrak{M}, f, \mathcal{K}, \bar{M}, w, r, v_0, D_c,\\ &\eta^{(c)}, \mathsf{BridgeSpec}_c, \delta_c, \beta_c,\\ &\Delta_{\mathrm{shift}}, \Delta_{\mathrm{abs}}, \Delta_{\mathrm{route}}, \Delta_{\mathrm{spec}}, \Delta_{\mathrm{other}}, T_{\mathrm{exp}}),\end{aligned}$$

where N identifies the immutable $\mathsf{NormSpec}$, c its protected harm or objective, and the three digests bind semantic evidence, numeric rules, and mission accounting; $\mathcal{K} \neq \varnothing$, $\bar{M} \in \mathbb{R}^{k\times k}_+$ with $K \leq \bar{M}$ for every $K \in \mathcal{K}$, $w \in \mathbb{R}^k_{>0}$, $r, v_0 \in [0, \infty)$, $Kw \leq rw$ uniformly, and $u_s w \leq \eta_{s,c}$, $\delta_c \in [0, 1]$ is the registered operational-risk target for c, $\beta_c \in [0, 1]$ allocates statistical miscoverage, $\Delta_{\mathrm{shift}}, \Delta_{\mathrm{abs}}$ are shift and abstraction slacks, $\Delta_{\mathrm{route}}, \Delta_{\mathrm{spec}}, \Delta_{\mathrm{other}}$ reserve quantified misses within enforced authority routes, lost constraints, and enumerated residual modes, and T_{exp} is the expiry condition. All five Δ-fields lie in $[0, 1]$. $\mathsf{BridgeSpec}_c$ binds measurable $H_{D_c,c}$, nonnegative measurable $L_{D_c,c}$ and $\{\ell_{d,c}\}$, $a_c \geq 0$, and $\{\xi_{d,c} \geq 0\}$, with $\mathbb{E}[\ell_{d,c} \mid \mathcal{F}_d] \leq a_c V_d + \xi_{d,c}$ and both consequence bridges in Theorem 5. A finite tag has $D_c \in \mathbb{N}_0$, $\eta^{(c)} = (\eta_{s,c})_{s=1}^{D_c}$ with $\eta_{s,c} \geq 0$, and finite bridge vectors. An open tag has $D_c = \infty$ and a finite proof object establishing $r < 1$, bounds on $\sum_{s\geq 1} \eta_{s,c}$ and $\sum_{d\geq 0} \xi_{d,c}$, and the infinite-horizon bridge. A finite tag cannot encode open authority. The mathematical tuple is not self-identifying: its operational binding record must name immutable versions or content digests for the protocol, models, prompts, tools, policies, and environment; the threat/ambiguity class and authority scope; the evidence snapshot, owner, and approval; the expiry condition; and every pre-certified fallback identity. Changing a bound field invalidates the binding unless covered ex ante.

A finite-horizon certificate may have $r \geq 1$; contraction alone is not an open-ended risk certificate. For a finite tag its theorem term is

$$C_{D_c,c} := a_c \left[v_0 S_{D_c}(r) + \sum_{s=1}^{D_c} \eta_{s,c} S_{D_c - s}(r) \right] + \sum_{d=0}^{D_c} \xi_{d,c},$$

with the corresponding $C_{\infty,c}$ for an open tag, and $\Delta_c := \Delta_{\text{shift}} + \Delta_{\text{abs}} + \Delta_{\text{route}} + \Delta_{\text{spec}} + \Delta_{\text{other}}$.

The vector w is a Lyapunov proof weight over hazard types. It is not a social-welfare weight and supplies no authority to trade one constituency's harm against another's. The operational certificate identifies two further immutable contracts. NumSpec defines the canonical numeric grammar, semantic ranges, input and intermediate ceilings, exact or directed-outward arithmetic, and comparison polarity used by every authorizing checker. BudgetSpec defines the unit of authority accounting, certified mission and trace language, horizon, durable risk-state machine, reservation and settlement rules, delegation semantics, and the pre-certified composition functional for repeated or concurrent authority. A probabilistic test also binds an attempt record and irreversible prechallenge debit as in Theorem 29. These contracts represent and consume established bounds; they supply no empirical evidence for a probabilistic premise.

For multiple protected constituencies, harms, or objectives, the scalar envelope is evaluated separately for every registered noncompensatory constraint. If $\mathcal{C}_{\mathsf{N}}$ is the complete finite nonempty protected set, the operational object is a bundle

$$\mathsf{CertBundle} = (\mathsf{N}, h(\mathsf{G}_{\text{evid}}), h(\mathsf{NumSpec}), h(\mathsf{BudgetSpec}), \{\mathsf{Cert}_c\}_{c \in \mathcal{C}_{\mathsf{N}}}, \beta_{\text{joint}}) .$$

Every member binds the same normative version, frozen evidence snapshot, numeric contract, budget contract, and current-epoch operator-family identities. Any mismatch invalidates the bundle. The value $\beta_{\text{joint}} \in [0, 1]$ covers all data-dependent quantities and multiplicity across the bundle, either by a direct joint event or allocations satisfying $\sum_c \beta_c \leq \beta_{\text{joint}}$. Authority requires $C_{D_c,c} + \Delta_c \leq \delta_c$ for every $c \in \mathcal{C}_{\mathsf{N}}$. The scalar theorems apply componentwise. The normative contract states whether it protects separate marginal events, their union, or both. Joint control of β_{joint} controls statistical miscoverage; it does not combine substantive harms. Scalar tradeoffs are permitted only when NormSpec expressly authorizes the aggregation rule and the disaggregated results remain in the decision record.

Operational use wraps this mathematical bundle in one canonical authenticated record:

$$\begin{aligned}\mathsf{ReleaseBinding} = (&\mathsf{schema}, \mathsf{releaseId}, \mathsf{releaseVersion}, \mathsf{releaseEpoch},\\ &\mathbf{h}_{\text{protocol/model/prompt/tool}},\\ &h(\mathsf{policy}), h(\mathsf{environment}), h(\mathsf{ThreatSpec}), h(\mathsf{StrategySpec}),\\ &\mathsf{authorityScope}, h(\mathsf{NormSpec}), h(\mathsf{DataFlowSpec}),\\ &h(\mathsf{HashSpec}), h(\mathsf{TCBSpec}), h(\mathsf{G}_{\text{evid}}),\\ &h(\mathsf{NumSpec}), h(\mathsf{BudgetSpec}), h(\mathsf{CertBundle}),\\ &h(\mathsf{EndpointInventory}), h(\mathsf{PortfolioSpec}),\\ &\mathsf{portfolioSlotId}, h(\mathsf{contextPredicate}),\\ &h(\mathsf{checkerSet}), h(\mathsf{KernelLimits0}), h(\mathsf{metaRiskRule}),\\ &\mathsf{owner}, h(\mathsf{approval}), \mathsf{validFrom}, \mathsf{expires}, \mathsf{invalidatingEpochs}, \mathbf{h}_{\text{fallbacks}}).\end{aligned}$$

The stack-digest vector identifies every participating protocol, model, prompt, and tool version. EndpointInventory is an authenticated, versioned, closed-world endpoint-set root with action-schema roots, actuator and provider account, credentials and grants, effect and idempotency receipts, reconciliation, emergency, invalidation, and mediation bindings. Registered authorityScope binds principal, tenant/owner, purpose, and authenticated grant chain; neither subject nor ambient credential grants it. PortfolioSpec identifies a bundle-wide joint audit event or preregistered meta-error allocations, their finite slots, owner, validity, and $\beta_{\text{portfolio}}$. It binds the certificate bundle and audit-event identity but does not hash ReleaseBinding, which avoids a digest cycle. The binding's registered meta-risk rule says whether operational risk alone or an all-in expression is compared with each protected target. In the all-in mode, the checker outwardly evaluates $\bar{\delta}_{\text{op},c} + (1 - \bar{\delta}_{\text{op},c})\beta_{\text{joint}}$ against the registered all-in target for c; a portfolio allocation applies the corresponding preregistered joint event or meta-error

rule. A change to any field creates a new binding and invalidates dependent summaries, runtime state, and leases. The versioned HashSpec fixes canonical typed framing, domain separation, digest and signature algorithms, key purposes, and the assumed collision and unforgeability properties. No security-relevant default or reply destination may remain outside those encodings. TCBSpec binds source, binary, configuration, and runtime identities; anchors; boot, update, rotation, and recovery; root domains and thresholds; ledger membership, non-equivocation, finality, and rollback; clock uncertainty; and expiry. It inventories premises, not honesty.

The numerical margin is valid only with its registered ambiguity class, coalition budget, observability model and expiry condition. These assumptions remain part of the certificate whenever it is used. Any update to an agent policy, memory process, prompt, retrieval source, reviewer pool, routing rule, tool schema, world model, TCB membership or configuration, endpoint effect profile, or authority-kernel code starts a new epoch unless the change lies inside the predeclared ambiguity and operator families. Authority resumes only after the affected evidence and binding records have been re-established.

B CONDITIONAL SAFETY ENVELOPES

The central theorem converts a local, full-history conditional contract into an end-to-end risk envelope. It permits adaptive topology switching, dependent siblings, strategic coalitions already quantified in the interface, and hazards created exogenously during the mission. The supermartingale argument tracks $V_d = Z_d w$, a weighted count of live hazards: each depth multiplies its conditional expectation by at most r and adds at most η, and Markov's inequality converts the expected count into the probability that any hazard is still live. Nothing in the argument requires hazards to be independent of one another.

Theorem 5 (Switched hazard contraction with immigration)**.** *Let $Z_d \in \mathbb{N}_0^k$ be $\mathcal{F}_d$-measurable and suppose Equation (12) holds under every admissible environment and coalition strategy. Let $w \in \mathbb{R}^k_{>0}$ and $r \geq 0$ satisfy*

$$Kw \leq rw \qquad \text{for every } K \in \mathcal{K},$$

put $V_d = Z_d w$, $w_{\min} = \min_i w_i$, and assume

$$\sup_{\text{admissible}} \mathbb{E}[V_0] \leq v_0 < \infty, \qquad u_s w \leq \eta_s \quad \text{almost surely}$$

for deterministic $\eta_s \geq 0$. Powers use $r^0 = 1$, including when $r = 0$. Then, for every $d \geq 0$,

$$\sup_{\text{admissible}} \mathbb{E}[V_d] \leq r^d v_0 + \sum_{s=1}^{d} r^{d-s}\eta_s, \tag{14}$$

$$\sup_{\text{admissible}} \mathbb{P}(Z_d \neq 0) \leq \min\left\{1, \frac{r^d v_0 + \sum_{s=1}^{d} r^{d-s}\eta_s}{w_{\min}}\right\}. \tag{15}$$

If nonnegative emitted losses satisfy $\mathbb{E}[\ell_d \mid \mathcal{F}_d] \leq cV_d + \xi_d$, for deterministic $c \geq 0$ and $\xi_d \geq 0$, define $S_j(r) = \sum_{h=0}^{j} r^h$. For every finite horizon D,

$$\sup_{\text{admissible}} \mathbb{E}\left[\sum_{d=0}^{D} \ell_d\right] \leq c\left[v_0 S_D(r) + \sum_{s=1}^{D} \eta_s S_{D-s}(r)\right] + \sum_{d=0}^{D} \xi_d. \tag{16}$$

If the registered depth-D mission event H_D is measurable, its registered severity $L_D \geq 0$ is measurable, and $L_D \leq \sum_{d=0}^{D} \ell_d$ and $\mathbf{1}_{H_D} \leq \sum_{d=0}^{D} \ell_d$, the same right-hand side bounds robust expected severity and robust catastrophic probability.

Proof. Multiplying the interface by $w > 0$ gives, almost surely,

$$\mathbb{E}[V_{d+1} \mid \mathcal{F}_d] \leq Z_d K_d w + u_{d+1} w \leq r V_d + \eta_{d+1}.$$

Taking expectations and iterating proves Equation (14). On $Z_d \neq 0$, $V_d \geq w_{\min}$, so Markov's inequality proves Equation (15). Next $\mathbb{E}[\ell_d] \leq c\mathbb{E}[V_d] + \xi_d$. Summing over d and reversing the finite double sum yields

$$\sum_{d=0}^{D} \mathbb{E}[V_d] \leq v_0 S_D(r) + \sum_{s=1}^{D} \eta_s S_{D-s}(r),$$

which proves Equation (16); the two bridge claims follow by taking expectations. □

The almost-sure injection bound is sufficient but not necessary for the displayed conclusions: after taking expectations they depend on u_s only through $\mathbb{E}[u_s w]$, so $\sup_{\text{admissible}} \mathbb{E}[u_s w] \le \eta_s$ suffices for Equations (14) to (16). The pathwise form is what a kernel can check history by history and what a conditional application, valid from every certified history, requires; a certificate must say which form it registers. Section L gives a componentwise fixed-matrix refinement.

Finite missions and open-ended operation. The finite-horizon conclusion does not require $r < 1$. When $r < 1$ and $\sum_{s\ge1} \eta_s < \infty$, a uniform geometric bound follows:

$$\sum_{d\ge0} \mathbb{E}[V_d] \le \frac{v_0 + \sum_{s\ge1} \eta_s}{1-r}.$$

If also $\sum_{d\ge0} \xi_d < \infty$ and the infinite-horizon bridges obey

$$L_\infty \le \sum_{d\ge0} \ell_d, \qquad \mathbf{1}_{H_\infty} \le \sum_{d\ge0} \ell_d,$$

then monotone convergence and the theorem give the open-ended envelope

$$\sup_{\text{admissible}} \mathbb{E}[L_\infty] \le C_\infty, \qquad \sup_{\text{admissible}} \mathbb{P}(H_\infty) \le C_\infty, \quad C_\infty = \frac{c}{1-r}\left(v_0 + \sum_{s\ge1} \eta_s\right) + \sum_{d\ge0} \xi_d.$$

Persistent positive immigration generally leaves positive steady hazard mass and infinite cumulative loss even when propagation is contractive.

B.1 What the rate means

For a singleton exact mean operator K, Collatz–Wielandt gives

$$R_{\mathrm{CLF}}(\{K\}) = \rho(K) = \inf_{w>0} \max_i \frac{(Kw)_i}{w_i}.$$

For a switching family, $R_{\mathrm{CLF}}(\mathcal{K}) < 1$ exactly when some common positive-linear certificate $Kw \le rw$, $r < 1$, exists. This is a sufficient common-linear certificate. It is distinct from the joint spectral radius of deterministic matrix products; restricted switching can also admit other certificates.

Individual subcritical radii do not certify arbitrary switching. For

$$K_1 = \begin{pmatrix} 0 & a \\ 0 & 0 \end{pmatrix}, \qquad K_2 = \begin{pmatrix} 0 & 0 \\ a & 0 \end{pmatrix},$$

each radius is zero, while alternating produces $\rho(K_1K_2) = a^2$. A componentwise envelope $\bar{M} \ge K$ for all $K \in \mathcal{K}$ gives the potentially loose infimal envelope rate $\bar{R} = \rho(\bar{M})$. Every $r > \bar{R}$ is checkable using $(rI - \bar{M})^{-1}\mathbf{1} > 0$; equality needs a positive super-eigenvector. Even the zero process can be dominated by many matrices, so $\bar{R}$ must never be called an intrinsic reproduction number.

Example 6 (Stable deterministic products can hide stochastic growth). Let

$$K_1 = \begin{pmatrix} .6 & .6 \\ 0 & 0 \end{pmatrix}, \qquad K_2 = \begin{pmatrix} 0 & 0 \\ .6 & .6 \end{pmatrix}.$$

Every length-d product has growth rate $.6^d$ up to a fixed norm factor, so the joint spectral radius is .6. Nevertheless, a stochastic process satisfying the conditional mean interface can be supercritical. Keep each nonzero population concentrated in one type. Given z individuals of that type, draw $N \sim \mathrm{Bin}(2z, .6)$ and independently assign the entire next population to either type with probability $1/2$. Select K_1 in type 1 and K_2 in type 2. Then $\mathbb{E}[Z_{d+1} \mid \mathcal{F}_d] = (.6z, .6z) = Z_d K_d$, while the total population is an exact Galton–Watson process of mean 1.2. Its survival probability is positive. The common-linear infimum is 1.2, since the two row inequalities require $r \ge .6 + .6 \max\{w_2/w_1, w_1/w_2\}$. Thus deterministic switched stability cannot replace the history-conditioned stochastic certificate.

Corollary 7 (Homogeneous certified margin)**.** *Suppose, uniformly over each pre-fan-out history, every live hazard creates at most $b > 0$ hazardous descendants in conditional expectation. Conditional on the complete proposal/fan-out realization and all earlier descendant outcomes, suppose every descendant passes $s \in \mathbb{N}_0$ checkpoint interfaces with full-history escape bounds $\epsilon_1, \dots, \epsilon_s \in [0, 1]$. Then the supplied scalar envelope is*

$$\bar{R} = b \prod_{\ell=1}^{s} \epsilon_\ell = \exp\left(\log b - \sum_{\ell=1}^{s} I_\ell \right), \qquad I_\ell = -\log \epsilon_\ell.$$

Its certified margin

$$\Gamma_{\mathrm{cert}} := -\log \bar{R} = \sum_{\ell=1}^{s} I_\ell - \log b$$

is attained with $w = 1, r = \bar{R}$ and is positive exactly when this scalar envelope contracts. With no immigration, unit potential, and initial source bound v_0, terminal breakthrough at depth d is at most $v_0 \bar{R}^d$. The extension to fan-out bound $b = 0$ has $\bar{R} = 0$ and $\Gamma_{\mathrm{cert}} = +\infty$ directly, without using $\log b$.

The equation prices checkpoint evidence and authority in the same logarithmic unit. A deeper hierarchy is not intrinsically unsafe; adding an agent helps only when the conditional evidence it supplies exceeds the hazardous fan-out it enables. Restricting tool authority or subdelegation reduces $\log b$ even when model accuracy is unchanged.

B.2 Sharpness for an exact branching process

Theorem 8 (Branching phase transition)**.** *Starting from one live hazard, consider the one-type construction in which, for $\alpha \in [0, 1]$, each hazard independently has* $\mathrm{Binomial}(b, \alpha)$ *escaped children, for positive integer b. Its exact process reproduction mean is $R_{\mathrm{proc}} = b\alpha$.*

1. *If $R_{\mathrm{proc}} \le 1$ and the offspring law is nonsingular ($\mathbb{P}(N = 1) \neq 1$), the cascade becomes extinct almost surely.*
2. *If $R_{\mathrm{proc}} > 1$, it survives forever with probability $1 - q > 0$, where q is the smallest solution in $[0, 1]$ of $q = (1 - \alpha + \alpha q)^b$.*
3. *More generally, for integrable $\mathbb{N}_0$-valued Z_0 independent of the i.i.d. offspring family, with every initial individual governed by the same law, $\mathbb{E}[Z_d] = R_{\mathrm{proc}}^d \mathbb{E}[Z_0]$.*

The analogous criterion for an irreducible, nonsingular multitype Galton–Watson process uses the spectral radius of its exact *mean operator.*

Proof. These are the classical extinction and mean-growth theorems (Athreya & Ney, 1972; Harris, 1963). The offspring generating function is $(1 - \alpha + \alpha s)^b$, and conditional independence gives $\mathbb{E}[Z_{d+1} \mid Z_d] = b\alpha Z_d$. □

This construction establishes sharpness within the admitted class; Theorem 5 itself permits dependent hazards. It shows that above the mean boundary, local mean-interface facts alone cannot rule out unbounded propagation. Survival is not itself catastrophe; a consequence bridge is still required.

B.3 Power-seeking incentives and authority containment

The original POWER definition measures normalized average optimal value. The 2021 paper's Proposition 6.9 requires a copy relation between attainable state-visitation sets and additional reachability conditions; Theorem 6.13 concerns average-optimal recurrent-state distributions under copy and disjoint support conditions (Turner et al., 2021). Both conclude an orbit majority in the sense of that paper's Definition 6.5, which counts strict inequalities over the permutation orbit and excludes ties. Cardinality of raw actions or states alone supplies neither premise. Our following result uses a registered POWER measure to identify a consequence class; it requires no incentive prediction about the particular deployed agent.

Definition 9 (Registered instrumental-power bridge)**.** Let a finite rewardless MDP $\mathcal{M}_{\mathrm{pow}}$ have nonempty state set $\mathcal{S}_{\mathrm{pow}}$, nonempty action sets $\mathcal{A}_{\mathrm{pow}}(x)$, and kernel P_{pow}. For a bounded-support law D_R on $\mathbb{R}^{\mathcal{S}_{\mathrm{pow}}}$ and $\gamma \in (0,1)$, define Turner et al.'s state power

$$\mathrm{POWER}_{\mathsf{D}_R}(x,\gamma) := \frac{1-\gamma}{\gamma}\mathbb{E}_{R\sim\mathsf{D}_R}[V_R^*(x,\gamma) - R(x)]\,. \tag{17}$$

For $a \in \mathcal{A}_{\mathrm{pow}}(x)$, put $\mathsf{p}(x,a) := \mathbb{E}_{X'\sim P_{\mathrm{pow}}(x,a)}[\mathrm{POWER}_{\mathsf{D}_R}(X',\gamma)]$. Relative to a registered available baseline $a^0(x)$, a is Turner-relative power-seeking when $\mathsf{p}(x,a) \geq \mathsf{p}(x,a^0(x))$.

Write $\mathcal{A}^{\mathrm{OSG}}(s)$ for the enabled complete concrete joint-action set, including the orchestrator decision. Jointly measurable ψ and ϕ, with $\psi : \mathcal{S} \to \mathcal{S}_{\mathrm{pow}}$ and $\phi(s,a) \in \mathcal{A}_{\mathrm{pow}}(\psi(s))$, map concrete states and actions into the registered MDP. At each proof history h, with state $s = s(h)$, a registered coupling or discrepancy bound compares $\psi_{\#}P^{\mathrm{OSG}}(\cdot \mid h,a)$ with $P_{\mathrm{pow}}(\cdot \mid \psi(s),\phi(s,a))$; the maps alone imply neither dynamical equality nor effect mediation.

Put $X_t = \psi(S_t)$, adapted to $\mathcal{F}_t^{\mathrm{OSG}}$. For $T_{\mathrm{pow}} \in \mathbb{N}_0 \cup \{\infty\}$ and cap $\tau \in \mathbb{R}$, let $C_\tau = \{x : \mathrm{POWER}_{\mathsf{D}_R}(x,\gamma) > \tau\}$ and define

$$\kappa_\tau := \inf\{t \in \mathbb{N}_0 : t \leq T_{\mathrm{pow}},\ X_t \in C_\tau\}, \qquad H^{\mathrm{pow}}_{\tau,T_{\mathrm{pow}}} := \{\kappa_\tau < \infty\}, \tag{18}$$

with $\inf \varnothing = \infty$. The reward law, reward units, discount, and cap are fixed together; an affine reward change can change the cap test. This is an $\mathcal{F}_t^{\mathrm{OSG}}$-stopping time and includes an initially over-cap state; it need not be observable to the deployed orchestrator.

On crossing, a precommitted compiler places every initial entry or first crossing and its downstream authority effects in a causal graph. For $D_{\mathrm{del}}, Q_{\mathrm{pow}} \in \mathbb{N}_0 \cup \{\infty\}$, the former bounds delegation per route; the latter is a distinct topological rank also ordering later primitive-time admissions, retries, and dependencies. Filtration $\mathcal{G}_q^{\mathrm{pow}}$ reveals complete history through rank q, but no future outcomes. Event $H^{\mathrm{auth}}_{T_{\mathrm{pow}}}$ and normalized severity $L^{\mathrm{auth}}_{T_{\mathrm{pow}}} \in [0,1]$ are measurable and record, through this rank, unacceptable realized external authority effects attributable to it. Attribution is the registered ancestor relation in that causal graph. Effects outside it require a separate harm class or miss reserve. The PowerSpec binds all objects, full-law class, route cover, online predicate, bridge, evidence, owner, expiry, and digest. Only authenticated observable traces earn credit for latent crossings; false negatives and unmapped or unmediated routes are misses. No map infers motive or a horizon; an unreachable cap is vacuous.

Corollary 10 (Instrumental-power containment under mediated authority)**.** *Fix a* PowerSpec *with finite primitive, delegation, and causal horizons. Let $\mathcal{P}_{\mathrm{pow}} \neq \varnothing$ contain all joint laws from admitted environments, coalition strategies, and adaptive proposal, routing, or stopping policies;* $\sup_P$ *ranges over it. Let $Z_q^{\uparrow} \in \mathbb{N}_0$ count live artifacts after rank-q gates. Uniformly over this class and certified reachable histories, suppose*

$$\mathbb{E}_P[Z_{q+1}^{\uparrow} \mid \mathcal{G}_q^{\mathrm{pow}}] \leq rZ_q^{\uparrow} + \eta_{q+1}, \qquad r = b\alpha, \tag{19}$$

for $0 \leq q < Q_{\mathrm{pow}}$. Given $\mathcal{G}_q^{\mathrm{pow}}$, $b \geq 0$ bounds expected proposals per live artifact and $\alpha \in [0,1]$ each admission chance conditional on the proposals, full history, and prior outcomes; otherwise r directly bounds the joint kernel. Also $\sup_P \mathbb{E}_P[Z_0^{\uparrow}] \leq v_0$, and deterministic $\eta_s \geq 0$ includes later first-crossing admissions.

Let U_{miss} include abstraction or monitor misses, trace failures, off-path acquisition, and uncovered or unmediated routes, with $\sup_P P(U_{\mathrm{miss}}) \leq \Delta_{\mathrm{pow}} \in [0,1]$. Off it, complete mediation and counting persist until every alias is neutralized or charged. For deterministic $c, \xi_q \geq 0$, let nonnegative ℓ_q^{pow} obey

$$\max\Big\{\mathbf{1}_{H^{\mathrm{auth}}_{T_{\mathrm{pow}}}\setminus U_{\mathrm{miss}}}, L^{\mathrm{auth}}_{T_{\mathrm{pow}}}\mathbf{1}_{U^c_{\mathrm{miss}}}\Big\} \leq \sum_{q=0}^{Q_{\mathrm{pow}}} \ell_q^{\mathrm{pow}},$$
$$\mathbb{E}_P[\ell_q^{\mathrm{pow}} \mid \mathcal{G}_q^{\mathrm{pow}}] \leq cZ_q^{\uparrow} + \xi_q.$$

Then

$$\sup_P P(H^{\mathrm{auth}}_{T_{\mathrm{pow}}}) \leq \min\{1, C^{\mathrm{pow}}_{Q_{\mathrm{pow}}} + \Delta_{\mathrm{pow}}\}, \tag{20}$$

$$C^{\mathrm{pow}}_{Q_{\mathrm{pow}}} := c\left[v_0 S_{Q_{\mathrm{pow}}}(r) + \sum_{s=1}^{Q_{\mathrm{pow}}} \eta_s S_{Q_{\mathrm{pow}}-s}(r)\right] + \sum_{q=0}^{Q_{\mathrm{pow}}} \xi_q.$$

It also bounds $\sup_P \mathbb{E}_P[L^{\text{auth}}_{T_{\text{pow}}}]$. *With no injection,* $\sup_P \mathbb{E}_P[Z_q^{\uparrow}] \le r^q v_0$. *Only the exact Theorem 8 witness makes* $b\alpha = 1$ *a critical mean; otherwise* $r < 1$ *is merely certificate contraction. Open branches compile to* $Q_{\text{pow}} = \infty$, *requiring* $r < 1$, *summable injection and loss, infinite bridges, and one global, nonreused miss reserve.*

Proof. For each P, apply Theorem 5 on the original probability space with $D = Q_{\text{pow}}$, $H_D := H^{\text{auth}}_{T_{\text{pow}}} \setminus U_{\text{miss}}$, and $L_D := L^{\text{auth}}_{T_{\text{pow}}} \mathbf{1}_{U^c_{\text{miss}}}$. The displayed bridge bounds their probability and expectation by $C^{\text{pow}}_{Q_{\text{pow}}}$. Since $L^{\text{auth}}_{T_{\text{pow}}} \le 1$, adding $P(U_{\text{miss}}) \le \Delta_{\text{pow}}$ proves both finite claims without future-miss conditioning; the open claims follow from the open envelope. □

Incentives versus consequences. POWER preference may persist when mediation makes $H^{\text{auth}} = 0$, while an unmediated cached bypass can harm at $r = 0$. Thus the corollary neither suppresses nor refutes Turner: it bounds unconditional consequences; an authorization-conditioned claim needs a registered joint or division-free bridge. Section C.4 separately derives local consent bounds from stronger conditional preference and voting premises; it does not alter this corollary's consequence-only conclusion.

B.4 Recovery under enforced isolation

Corollary 11 (Recovery under isolation)**.** *Let* τ *be an almost surely finite,* $\mathbb{N}_0$*-valued alarm stopping time. Conditional on* $\mathcal{F}_\tau$, *suppose the switched interface continues on the shifted filtration throughout recovery, with no further immigration and an operator family having common* $w > 0$ *and* $0 \le r_{\text{rec}} < 1$. *Define the recovery potential* $V_{\tau+s} = Z_{\tau+s} w$, *and let*

$$T_{\text{rec}} = \inf\{s \in \mathbb{N}_0 : Z_{\tau+s} = 0\} \in \mathbb{N}_0 \cup \{\infty\}.$$

Then zero is absorbing and, for every integer $T \ge 0$,

$$\mathbb{P}(T_{\text{rec}} > T \mid \mathcal{F}_\tau) \le \min\left\{1, \frac{r^T_{\text{rec}} V_\tau}{w_{\min}}\right\}. \tag{21}$$

where $r^0_{\text{rec}} = 1$, *including at* $r_{\text{rec}} = 0$. *Thus* $T_{\text{rec}} < \infty$ *almost surely. If post-alarm loss obeys* $\mathbb{E}[\ell_{\tau+s} \mid \mathcal{F}_{\tau+s}] \le c_{\text{rec}} V_{\tau+s}$ *for* $c_{\text{rec}} \ge 0$, *then*

$$\mathbb{E}\left[\sum_{s\ge 0} \ell_{\tau+s} \,\middle|\, \mathcal{F}_\tau\right] \le \frac{c_{\text{rec}} V_\tau}{1 - r_{\text{rec}}}. \tag{22}$$

If $V_\tau = 0$, *then* $T = 0$ *is a conditional recovery deadline with failure probability zero. If* $V_\tau > 0$ *and* $r_{\text{rec}} = 0$, *then* $T = 1$ *is a conditional recovery deadline with failure probability zero. If* $V_\tau > 0$, $0 < r_{\text{rec}} < 1$, *and* $\varepsilon \in (0, 1)$, *a conditional recovery deadline with failure probability at most* ε *is*

$$T \ge \left\lceil \frac{[\log(V_\tau/(\varepsilon w_{\min}))]_+}{-\log r_{\text{rec}}} \right\rceil.$$

Proof. Apply Theorem 5 conditionally after τ. With no immigration, nonnegativity makes $Z = 0$ absorbing, so $\{T_{\text{rec}} > T\} = \{Z_{\tau+T} \ne 0\}$. The conditional version of Equation (15) proves the tail and almost-sure recovery. Solving the tail inequality gives the deadline; summing the conditional geometric loss bound gives Equation (22). □

The deadline controls a tail probability. A uniform deadline also needs an enforceable cap on V_τ. Isolation is essential: rollback that can create hazards needs an injection term. The declared recovered set must include latent corruption represented in Z; the theorem cannot repair omitted state.

B.5 Finite authority-route certificates and containment

Some systems have a fixed, shallow execution DAG. Let $\mathcal{P}$ be the registered finite set of its minimal hazardous source-to-authority routes. If $\mathcal{P} = \varnothing$, the displayed bridges require H empty and $L = 0$; an empty gate product equals one. Route p has $k_p \in \mathbb{N}_0$ gates, a route-selection event Q_p, source-hazard

event S_p, joint selected-source bound $\lambda_p \in [0,1]$, conditional gate escapes $\epsilon_{p1}, \dots, \epsilon_{pk_p} \in [0,1]$, and loss cap $c_p \geq 0$. Let A_{pj} be the j-th escape event and $B_p = Q_p \cap S_p \cap \bigcap_{j=1}^{k_p} A_{pj}$ its breakthrough event. Write $\mathcal{F}_{pj^-}$ for the complete proof sigma-field immediately before gate j on route p.

Proposition 12 (Finite-route authority certificate)**.** *Assume $\mathbb{P}(Q_p \cap S_p) \leq \lambda_p$. Put $E_{pj} = Q_p \cap S_p \cap \bigcap_{i<j} A_{pi} \in \mathcal{F}_{pj^-}$, and assume, for the complete pre-gate history,*

$$\mathbb{E}[\mathbf{1}_{A_{pj}} \mathbf{1}_{E_{pj}} \mid \mathcal{F}_{pj^-}] \leq \epsilon_{pj} \mathbb{E}[\mathbf{1}_{E_{pj}} \mid \mathcal{F}_{pj^-}]$$

almost surely. If the catastrophe and severity bridges are

$$H \subseteq \bigcup_{p \in \mathcal{P}} B_p, \qquad L \leq \sum_{p \in \mathcal{P}} c_p \mathbf{1}_{B_p},$$

then

$$\mathbb{P}(H) \leq \min\left\{1, \sum_{p \in \mathcal{P}} \lambda_p \prod_{j=1}^{k_p} \epsilon_{pj}\right\}, \tag{23}$$

$$\mathbb{E}[L] \leq \sum_{p \in \mathcal{P}} c_p \lambda_p \prod_{j=1}^{k_p} \epsilon_{pj}. \tag{24}$$

Section M.1 gives the proof; no route independence is needed. This form requires Q_p to be decided before the first gate. For later adaptive routing, compile each route choice as a prefix gate, with its conditional selection bound (or one), and apply the chain rule to the successively revealed prefix. A source bound can then be multiplied by these prefix and escape bounds; a retrospectively selected complete route cannot receive an unproved marginal selection discount. Compartments enter through c_p, the maximum authority or irreversible loss reachable from a route, so a weak gate may be acceptable before a read-only tool and unacceptable before funds transfer, deployment, or credential release. If $\mathcal{P}$ covers only a declared subset of authority routes, the first bridge must be softened to $H \subseteq U_{\text{route}} \cup \bigcup_p B_p$ and the uncovered mass charged to Δ_{route} in Theorem 35. Route omission is not zero risk.

Lemma 13 (Constraint-survival accounting)**.** *For $d \in \mathbb{N}$, consider a depth-d interface chain and let R_j denote retention of a binding safety constraint through hop j. Suppose, uniformly over every reachable history on which the constraint has survived the earlier hops, for $\varepsilon_j^{\text{spec}} \in [0,1]$,*

$$\mathbb{E}[\mathbf{1}_{R_j} \mathbf{1}_{E_j} \mid \mathcal{F}_{j-1}] \geq (1 - \varepsilon_j^{\text{spec}}) \mathbb{E}[\mathbf{1}_{E_j} \mid \mathcal{F}_{j-1}], \qquad E_j := \bigcap_{i<j} R_i \in \mathcal{F}_{j-1}.$$

Then

$$\mathbb{P}(R_1 \cap \cdots \cap R_d) \geq \prod_{j=1}^{d} (1 - \varepsilon_j^{\text{spec}}), \qquad \mathbb{P}\left(\bigcup_{j=1}^{d} R_j^c\right) \leq 1 - \prod_{j=1}^{d} (1 - \varepsilon_j^{\text{spec}}) \leq \sum_{j=1}^{d} \varepsilon_j^{\text{spec}}.$$

Proof. The probability chain rule gives the product lower bound; complementation and the union bound give the remaining inequalities. □

Lemma 13 is accounting, not a safety theorem. Specification loss causes catastrophe only through a declared consequence bridge. Conservatively, its entire probability mass can be charged to Δ_{spec}. More structurally, a loss that creates a hazard from an otherwise clean parent belongs in the injection term u_d, whereas a loss downstream of an existing live hazard belongs in the propagation operator K_d. Conversely, a surviving constraint does not make the action safe. Charging the same consequence inside K_d or u_d and again as Δ_{spec} remains conservative, but it is a redundant debit and must be disclosed.

B.6 WHAT MUST BE MEASURED

The calculus requires evidence for seven distinct claims.

1. Catastrophe, hazard, and severity predicates precise enough to support the declared consequence bridges.
2. A complete authority-route graph, including route-selection events, permissions, retries, and indirect tool effects.
3. A worst-case or high-confidence fan-out envelope, including retries, shared memory, and indirect tool effects.
4. Full-history conditional escape and reviewer dependence after adaptive upstream selection.
5. Exogenous hazard creation and constraint loss, classified relative to clean versus already-live parent state.
6. Simultaneous abstraction, shift, uncovered-route, and residual-mode bounds, including the meta-error of every estimated reserve.
7. Authority/loss weights, ambiguity class, horizon, trusted enforcement boundary, and expiry rule.

The lower bounds in Section F show why ordinary held-out component accuracy cannot silently discharge these obligations.

C COALITION- AND DEPENDENCE-AWARE OVERSIGHT

The quorum bound gives a conditional escape exponent for K_d. It accounts for adversarial votes by strategic reviewers and correlated semantic errors among nominally honest reviewers.

C.1 A DEPENDENCY-GRAPH QUORUM BOUND

Consider a q-of-n gate with $0 \le f < n$ and $1 \le q \le n$. At most f authenticated identities are Byzantine; for worst-case false authorization they all vote "approve." Let $m = n - f$ and $a = q - f$. Let the pre-vote history h include coalition identities, the entire Byzantine transcript, assignments, and every message available before honest votes. Conditional on h and a proposal's hazardous latent state $Y \in \{0, 1\}$, let $E_i = 1$ if remaining reviewer i erroneously approves it.

A graph G is a dependency graph for $E_1, \dots, E_m$ if disjoint vertex sets with no edge between them index independent variable families. Its chromatic number χ measures the evidence lost to worst-case dependence: m/χ is the theorem's effective evidence count. This is a structural assumption, not an estimate from pairwise correlations. Independent reviewers have $\chi = 1$; shared weights, training data, retrieval, prompts, or pre-vote discussion may make G complete and $\chi = m$. Operationally, m/χ is the number of reviewers whose votes count as independent evidence: five identical error variables require a complete graph, while five reviewers count as five independent observations only after their conditional joint independence has been established. Different model families and siloed context alone do not establish it.

Theorem 14 (Dependent Byzantine quorum)**.** *Suppose that, uniformly over every admissible full pre-vote history and hidden hazard state,*

$$\sum_{i=1}^{m} \mathbb{E}[E_i \mid h, Y = 1] \le \bar{\mu}$$

for $0 \le \bar{\mu} \le m$, and the conditional dependency graph has chromatic number at most $1 \le \chi \le m$. The graph and coloring are fixed or pre-vote measurable, and their conditional independence claim remains valid after the complete registered pre-vote transcript, coalition choice, realized fan-out, prior sibling outcomes, and adaptive reviewer assignment are revealed. Put $\bar{p} = \bar{\mu}/m$ and $\theta = a/m = (q - f)/(n - f)$. If $a \le 0$ or $\theta \le \bar{p}$, use the trivial false-authorization bound 1. Otherwise,

$$\mathbb{P}(\textit{authorize} \mid h, Y = 1) \le \exp\left[-\frac{m}{\chi} D_{\mathrm{Ber}}(\theta \| \bar{p})\right], \tag{25}$$

where

$$D_{\mathrm{Ber}}(x\|p) = x\log\frac{x}{p} + (1-x)\log\frac{1-x}{1-p}.$$

We use the standard lower-semicontinuous boundary conventions. If L checkpoint committees each satisfy Equation (25) conditional on every preceding committee having authorized, their joint escape probability is at most $\exp(-\sum_{\ell=1}^{L} I_\ell)$, where $I_\ell = (m_\ell/\chi_\ell)D_{\mathrm{Ber}}(\theta_\ell\|\bar{p}_\ell)$. No cross-stage independence is required.

Proof. False authorization requires $S = \sum_i E_i \geq a$. Properly color G into χ independent classes $C_1, \ldots, C_\chi$, and put $p_i = \mathbb{E}[E_i \mid h, Y = 1]$. For $\lambda > 0$, conditional Hölder and independence within each color give

$$\begin{aligned}\mathbb{E}[e^{\lambda S} \mid h, Y=1] &\leq \prod_{c=1}^{\chi} \mathbb{E}\Big[e^{\chi\lambda \sum_{i\in C_c} E_i} \mid h, Y=1\Big]^{1/\chi} \\ &= \prod_{i=1}^{m}(1 - p_i + p_i e^{\chi\lambda})^{1/\chi} \\ &\leq \big(1 + \bar{p}(e^{\chi\lambda} - 1)\big)^{m/\chi}.\end{aligned}$$

The last line is Jensen's inequality applied to the concave function $\log(1 + p(e^{\chi\lambda} - 1))$. Markov's inequality and optimization over $\chi\lambda$ yield Equation (25); this is the standard coloring/Hölder dependency-graph Chernoff argument (Janson, 2004). Serial composition follows from the probability chain rule and the stipulated full-history conditional bound. □

Remark 15 (Coalition size and post-vote corruption). Let the actual coalition have size $f' \leq f$, so that $M = n - f' \geq m$ reviewers are nonfaulty, with conditional means $p_i = \mathbb{E}[E_i \mid h, Y = 1]$ obeying the aggregate bound $\sum_{i\leq M} p_i \leq M\bar{p}$ and a conditional dependency graph on all M reviewers of chromatic number at most χ. A per-reviewer bound $p_i \leq \bar{p}$ implies the aggregate bound, and so does a bound $m\bar{p}$ on every m-subset, by averaging over subsets. Then Equation (25), computed at the budget f, remains valid. First, Theorem 14 applied to the actual configuration gives $\exp[-(M/\chi)D_{\mathrm{Ber}}(\theta'\|\bar{p})]$ with $\theta' = (q - f')/M \geq \theta$, and $g(f') := (n - f')D_{\mathrm{Ber}}((q - f')/(n - f')\|\bar{p})$ has derivative $-\log(\theta'/\bar{p}) < 0$ wherever $\theta' > \bar{p}$, so $g(f') \geq g(f)$ whenever $\theta > \bar{p}$; if $\theta \leq \bar{p}$ the budget bound is the trivial one. Second, by event domination: the m reviewers with the smallest means, ties broken by index, form a pre-vote-measurable set S with $\sum_{i\in S} p_i \leq (m/M)\sum_{i\leq M} p_i \leq m\bar{p}$; counting the other $M - m = f - f'$ nonfaulty votes as approvals dominates the actual approval count pointwise, so $\{\text{authorize}\} \subseteq \{\sum_{i\in S} E_i \geq q - f\}$, and the induced dependency subgraph on S has chromatic number at most χ. Not every m-subset inherits the aggregate bound: with $M = 3$, $\bar{p} = 1/3$, and means $(1, 0, 0)$, the subset $\{1, 2\}$ has sum $1 > 2\bar{p}$. If instead at most f identities can be corrupted *after* the honest votes are cast, let $E_1, \ldots, E_n$ be the ideal error indicators of all n identities, with $\sum_{i=1}^{n} p_i \leq n\bar{p}$ and a dependency graph on all n identities of chromatic number at most χ. False authorization then requires $\sum_{i=1}^{n} E_i \geq q - f$, and the same proof gives the bound $\exp[-(n/\chi)D_{\mathrm{Ber}}((q - f)/n\|\bar{p})]$ when $(q - f)/n > \bar{p}$. Its threshold fraction $(q - f)/n$ is strictly smaller than $\theta = (q - f)/(n - f)$ whenever $f \geq 1$ and $q > f$, and $mD_{\mathrm{Ber}}(a/m\|\bar{p})$ is strictly decreasing in m for fixed a whenever $a/m > \bar{p}$, since its derivative is $\log[(1 - a/m)/(1 - \bar{p})] < 0$. So the static formula cannot be reused in that threat model: for $n = 2, f = 1, q = 2$, the static bound is $\bar{p}$, while post-vote corruption of one independent vote passes with probability $2\bar{p} - \bar{p}^2$, the binomial expression $\mathbb{P}\{\mathrm{Bin}(n, \bar{p}) \geq q - f\}$ of Proposition 28, whose proof does not need $q \leq n - f$.

Proposition 16 (Conditional second-moment quorum fallback)**.** *Retain the full-history conditioning and Byzantine accounting of Theorem 14. Let $S = \sum_{i=1}^{m} E_i$, $m = n - f$, and $a = q - f$. Suppose that, uniformly over every admissible pre-vote history, hidden hazard state, and coalition choice,*

$$\mathbb{E}[S \mid h, Y = 1] \leq \bar{\mu}, \qquad \mathrm{Var}(S \mid h, Y = 1) \leq \bar{V}.$$

If $a > \bar{\mu}$, then

$$\mathbb{P}(\text{authorize} \mid h, Y = 1) \leq \frac{\bar{V}}{\bar{V} + (a - \bar{\mu})^2}. \tag{26}$$

If $a \le \bar{\mu}$, use the trivial bound one. In the homogeneous case, with every conditional marginal error equal to $p \in (0,1)$ and every pairwise covariance at most $\rho\sigma_i\sigma_j$ for $\rho \ge 0$ and the conditional standard deviations σ_i, one may take

$$\bar{\mu} = mp, \qquad \bar{V} = mp(1-p)[1+(m-1)\rho].$$

The same pair is valid when every marginal is merely at most p, provided $p \le 1/2$.

At the boundary $p = 0$, every honest error indicator is zero almost surely, so one may take $\bar{\mu} = \bar{V} = 0$ directly; a correlation coefficient is unnecessary and need not be defined. For $p > 1/2$ the variance expression requires the marginals to equal p: a single reviewer with marginal $1/2 \le 3/5$ has variance $1/4$, above the displayed $6/25$.

Proof. False authorization requires the honest sum to satisfy $S \ge a$. Conditional Cantelli applied to $S - \mathbb{E}[S \mid h, Y = 1]$ gives Equation (26). The homogeneous variance expression follows by summing the conditional variances and covariance upper bounds; when the marginals are only bounded by $p \le 1/2$, each variance is at most $p(1-p)$ because $x(1-x)$ increases on $[0, 1/2]$, and the right-hand side of Equation (26) increases in $\bar{V}$ and decreases in $a - \bar{\mu}$. □

Proposition 16 is an alternative weaker-tail assurance tier for cases where a sparse dependency graph cannot be defended. Its moment bounds must still hold after conditioning on coalition interaction and adaptive selection; unconditional empirical correlations are insufficient. The quantity $m/[1+(m-1)\rho]$ is a variance-equivalent diagnostic, not a universal effective sample size or tail law. The Cantelli bound and the dependency-graph exponent are alternatives, not independent evidence to be multiplied.

C.2 A MINIMAX-SHARP DEPENDENCE–COALITION BOUNDARY

Independent failure domains whose members err together attain the exponent of Theorem 14 up to its finite-size factor.

Definition 17 (Worst-case conditional quorum error)**.** Let $\mathcal{C}(m, p, \chi)$ contain Bernoulli vectors $E = (E_1, \dots, E_m)$ with $\sum_i \mathbb{E}E_i \le mp$ and a dependency graph of chromatic number at most χ. Define

$$A^\star(m, a, p, \chi) = \sup_{E \in \mathcal{C}(m,p,\chi)} \mathbb{P}\left(\sum_{i=1}^{m} E_i \ge a\right).$$

The supremum is conditional on any fixed admissible pre-vote history; in the orchestration application $m = n - f$ and $a = q - f$.

Theorem 18 (Minimax-sharp block-dependent Byzantine quorum)**.** *Assume $1 \le a \le m$, $0 < p < 1$, $1 \le \chi \le m$, $\chi \mid m$, and put*

$$g = m/\chi, \qquad \theta = a/m.$$

If $\theta > p$, then

$$A^\star(m, a, p, \chi) \le \exp[-gD_{\mathrm{Ber}}(\theta \| p)]. \tag{27}$$

For a matching construction, partition the reviewers into g blocks of size χ, draw $X_1, \dots, X_g$ independently from Bernoulli(p)*, and set every error in block j equal to X_j. Its exact false-authorization probability is*

$$\alpha_{\mathrm{blk}} = \mathbb{P}\{\mathrm{Binomial}(g, p) \ge t\}, \qquad t = \lceil a/\chi \rceil. \tag{28}$$

Writing $\vartheta = t/g$, when $\vartheta > p$,

$$\frac{e^{-gD_{\mathrm{Ber}}(\vartheta\|p)}}{g+1} \le \alpha_{\mathrm{blk}} \le e^{-gD_{\mathrm{Ber}}(\vartheta\|p)}. \tag{29}$$

In particular, if $\chi \mid a$, then $\vartheta = \theta$, so

$$\frac{e^{-gD_{\mathrm{Ber}}(\theta\|p)}}{g+1} \le A^\star(m, a, p, \chi) \le e^{-gD_{\mathrm{Ber}}(\theta\|p)}. \tag{30}$$

Thus, for fixed $\theta > p$ and $g \to \infty$, along sequences satisfying the stated divisibility conditions, the worst-case error exponent per independent failure domain converges to $D_{\mathrm{Ber}}(\theta\|p)$. The effective-evidence factor m/χ is minimax sharp up to a polynomial factor.

Proof. Theorem 14 gives Equation (27). In the construction, $\sum_i E_i = \chi \sum_j X_j$, which proves Equation (28); its dependency graph is the disjoint union of g cliques and has chromatic number χ. The upper half of Equation (29) is the binomial Chernoff bound. Keeping only the mass at t, and using the binary type bound $\binom{g}{t} \geq e^{gH(t/g)}/(g+1)$ gives the lower half. For completeness, t is a mode of $\mathrm{Bin}(g, t/g)$, so its mass is at least $1/(g+1)$, since there are $g+1$ possible counts. Rearranging that inequality proves the bound, including $t = 0, g$ by continuity. This is the binomial specialization of the method of types (Cover & Thomas, 2006). Now $p^t(1-p)^{g-t} = \exp[-g(H(\vartheta) + D_{\mathrm{Ber}}(\vartheta\|p))]$. Divisibility makes $\vartheta = \theta$; dividing the log sandwich by g proves the limit. □

Corollary 19 (Exponent-sharp orchestration phase boundary)**.** *Under Theorem 18, suppose every proposed child passes $L \in \mathbb{N}_{>0}$ serial q-of-n committees satisfying the same assumptions conditionally on the complete preceding history, including the realized proposal/fan-out collection and all earlier child outcomes. Suppose every live parent proposes at most $b > 0$ hazardous children in conditional expectation, uniformly over the corresponding pre-fan-out history. For every admissible protocol,*

$$\bar{\alpha}_{\mathrm{stack}} \leq e^{-LgD_{\mathrm{Ber}}(\theta\|p)}, \qquad \bar{R} = be^{-LgD_{\mathrm{Ber}}(\theta\|p)}. \tag{31}$$

Hence $\log b < LgD_{\mathrm{Ber}}(\theta\|p)$ universally certifies scalar propagation contraction. Interpreting this as an open-ended extinction phase also requires zero immigration; Theorem 5 handles nonzero injection separately.

Conversely, let every parent propose exactly $b \in \mathbb{N}$ children and use fresh, mutually independent block committees across serial stages, children, and parents. The exact offspring law is

$$N \sim \mathrm{Binomial}(b, \alpha_{\mathrm{blk}}^L), \qquad R_{\mathrm{blk}} = b\alpha_{\mathrm{blk}}^L.$$

If also $\chi \mid a$, then

$$\frac{b}{(g+1)^L} e^{-LgD_{\mathrm{Ber}}(\theta\|p)} \leq R_{\mathrm{blk}} \leq be^{-LgD_{\mathrm{Ber}}(\theta\|p)}. \tag{32}$$

Thus

$$\log b > LgD_{\mathrm{Ber}}(\theta\|p) + L\log(g+1)$$

exhibits an admissible supercritical process, whereas the universal certificate boundary differs only by the explicit $L\log(g+1)$ finite-size term. Exact survival occurs iff $b\alpha_{\mathrm{blk}}^L > 1$; catastrophe still requires a consequence bridge. If instead $b = 0$, propagation is identically zero and the logarithmic comparison is unnecessary.

Proof. The probability chain rule composes the L full-history upper bounds without independence. Multiplying by the fan-out bound proves the universal claim. Fresh randomness in the matching construction gives the displayed binomial offspring law. Raising Equation (30) to the L-th power proves Equation (32); the survival claim is Theorem 8. □

If $q \leq f$, Byzantine reviewers authorize alone and the soundness exponent is zero. If $\theta \leq p$, only the trivial universal upper bound one applies. Without $\chi \mid m$, the final smaller block produces a weighted Poisson-binomial tail; without $\chi \mid a$, the rounded ϑ in Equation (29) is the correct exponent. The lower construction is existential and uses fresh independence only to prove sharpness; the universal upper bound does not.

Safety–availability interval. For a benign proposal, assume every Byzantine reviewer withholds approval. Let $R_i = 1$ denote an honest false rejection, with total conditional mean at most $m\bar{\beta}$ and dependency chromatic number χ_0. The gate rejects if $\sum_i R_i \geq m - q + 1$. Applying Theorem 14 gives

$$\mathbb{P}(\text{reject} \mid Y = 0) \leq \exp\left[-\frac{m}{\chi_0} D_{\mathrm{Ber}}\left(\frac{m-q+1}{m} \middle\| \bar{\beta}\right)\right] \tag{33}$$

when $q \leq m$ and the displayed threshold exceeds $\bar{\beta}$; if $q > m$, Byzantine withholding guarantees rejection and the bound is 1. A usable q must make both Equations (25) and (33) small. Increasing q improves soundness but harms availability; increasing n helps only to the extent that it increases m/χ, the effective evidence diversity.

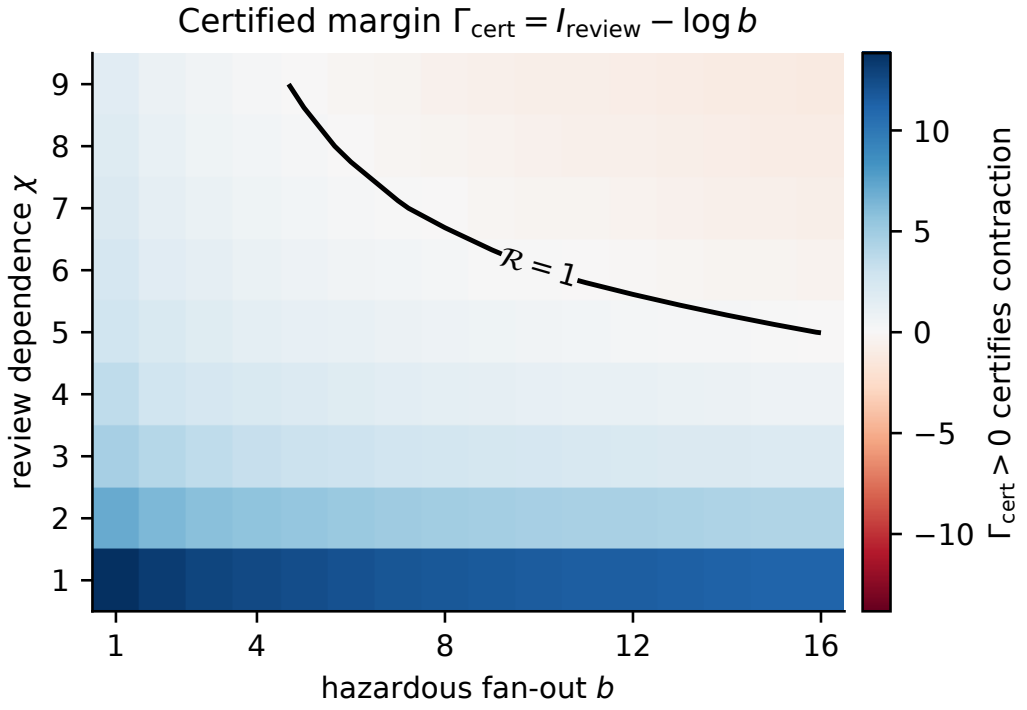

Figure 4: A certified risk envelope for $n = 25, f = 3, q = 16, p = .12$. The black contour is $\Gamma_{\text{cert}} = 0$. Higher hazardous fan-out or stronger review dependence can move an otherwise accurate committee into the noncontractive-envelope region; the figure does not identify the exact process phase.

Corollary 20 (Scalar orchestration risk envelope)**.** *For a homogeneous protocol with $L \in \mathbb{N}_{>0}$ identical committees per delegation level, honest conditional error at most p, hazardous fan-out $b > 0$, and $\theta = (q - f)/(n - f) > p$,*

$$\Gamma_{\text{cert}} = L\frac{n-f}{\chi} D_{\text{Ber}}(\theta \| p) - \log b. \tag{34}$$

Equivalently, the supplied envelope is $\bar{R} = e^{-\Gamma_{\text{cert}}}$, so the certificate *contracts when $\Gamma_{\text{cert}} > 0$; no intrinsic process margin is inferred from a chosen upper envelope. If there is no immigration, $\mathbb{E}Z_0 \le h_0$, and the terminal consequence bridge satisfies $\mathbb{P}(H \mid \mathcal{F}_D) \le cZ_D$, for $h_0, c \ge 0$, then, for $h_0 c > 0$, a depth-D target $\delta \in (0, 1]$, with $D \in \mathbb{N}_0$, is met for $0 < \bar{R} < \infty$ when*

$$D\Gamma_{\text{cert}} \ge \log(h_0 c/\delta).$$

If $\bar{R} = 0$, every depth $D \ge 1$ has zero terminal risk, while $D = 0$ requires $h_0 c \le \delta$; no product $0 \cdot \infty$ is used. If $h_0 c = 0$, the terminal target is met trivially.

Equation (34) places six engineering levers in one unit: coalition f, dependence χ, reviewer error p, threshold q, checkpoint redundancy L, and fan-out b.

C.3 Protocol design and strategic incentives

The assumptions behind Theorem 14 suggest six protocol requirements.

1. **Commit before assignment.** The proposer commits to a canonical plan and requested authority before reviewers are randomly drawn, limiting adaptive targeting.
2. **Authenticate failure domains.** Count model families, retrieval systems, prompts, vendors, and human teams when setting n, f, and G; API-call count alone does not identify independent evidence. Sybil replicas do not add evidence.

3. **Blind and silo first-round review.** Reviewers receive the minimum sufficient state and commit before discussion. This reduces persuasion and keeps a sparse dependency graph plausible.
4. **Separate safety from synthesis.** Critics output structured contract violations and evidence; an aggregation rule, not a persuasive agent, controls authority.
5. **Use audit anchors.** Randomly insert cases with externally verifiable labels and expose review decisions to delayed incident audits.
6. **Escalate disagreement.** A near-threshold or high-dependence committee does not average its way to confidence; it reduces authority or invokes a new failure domain.

The following contract gives a limited incentive guarantee; it does not solve unobservable truth.

Remark 21 (Audit-deterrence accounting). Suppose any utility-gaining deviation requires at least r_C members to file verifiably false reports, and its incremental utility is at most G_C. After commitment, each such report is conclusively audited with conditional probability at least a_{aud}, and a detected false report incurs transferable penalty F. Conditional on making the deviation, the coalition's expected incremental utility is at most $G_C - r_C a_{\text{aud}} F$. Hence every possibly randomized deviation is weakly unprofitable if $r_C a_{\text{aud}} F \geq G_C$, and strictly unprofitable if the inequality is strict and the deviation occurs with positive probability.

In the one-shot special case where unaudited concealment yields $U > 0$ and audited concealment yields $-c < 0$, take $G_C = U$, $r_C = 1$, and $F = U + c$. The strict-deterrence condition becomes $a_{\text{aud}} > U/(U + c)$. This exact threshold inherits all of Remark 21's assumptions about the stated conditional per-report audit probabilities, enforceable additive consequences, bounded utility, and absence of side payments or future retaliation; audit-event independence is not required for the expectation calculation.

This accounting applies to components whose effective utility can be bounded through payment, compute, access, continued deployment, or a trained reward. It does not apply to unbounded objectives, unverifiable semantics, or agents indifferent to penalties. Peer-prediction mechanisms can elicit information without labels (Prelec, 2004; Miller et al., 2005; Shnayder et al., 2016), but uninformative or collusive equilibria make them insufficient as a hard safety boundary. An incentive argument can justify a smaller admitted coalition class only when its utility, information, audit, and enforcement premises are proved. Observed cooperation alone cannot reduce the worst-case fault budget f.

Relation to Byzantine quorums. Classical $n \geq 3f + 1, q = 2f + 1$ quorum intersection prevents two conflicting certificates when honest identities never equivocate (Lamport et al., 1982; Castro & Liskov, 1999; Malkhi & Reiter, 1998). It does not make a semantically wrong certificate unlikely: honest reviewers can all share the same mistaken judgment. Theorem 14 controls semantic false authorization; Byzantine intersection controls equivocation. Consequential systems may need both. The exact authenticated-intersection calculation is recorded in Section M.3.

C.4 When power-seeking preferences supply oversight

An option-seeking agent can oppose another agent's acquisition when that acquisition removes options it values. A retargeting argument first bounds a preference probability. An enforced voting rule converts that preference into consent, and a quorum bound limits passage of a specified proposal. Shared gains need not face the same opposition, and a refusal is not automatically safe.

Fix a complete pre-vote history h, including the committed action, coalition, assignments, and previous outcomes. All probabilities below are conditional on h; for hazardous-action certification they also condition on its latent hazard state. A non-Byzantine rater follows a registered binary rule comparing two measurable scores for consent and refusal. Let C_j, R_j, T_j partition its parameter space into strict-consent, strict-refusal, and tie sets, with conditional law $\nu_{j,h}$. The parameter law must retain the stated uncertainty at this history. If a fixed deployed objective is already in the proof filtration, its conditional law is a point mass; an ex ante reward-orbit tendency then gives no nontrivial pointwise consent guarantee. Fresh assigned challenges below provide a constructive source of conditional randomness.

Proposition 22 (Retargeting with explicit ties)**.** *For each rater j, suppose $k_j \in \mathbb{N}_{>0}$ bimeasurable, measure-preserving bijections of its conditional parameter space send C_j into R_j, with pairwise disjoint images of C_j. Write $t_j = \nu_{j,h}(T_j)$. If ties consent, its consent indicator X_j satisfies*

$$\mathbb{P}(X_j = 1 \mid h) \le p_j := \frac{1 + k_j t_j}{k_j + 1}. \tag{35}$$

If ties refuse, the bound is $(1 - t_j)/(k_j + 1)$. In particular, $1/(k_j + 1)$ is valid for either rule when ties have zero probability.

Proof. The disjoint images have total mass $k_j \nu_{j,h}(C_j)$ and lie in R_j. Thus $\nu_{j,h}(R_j) \ge k_j \nu_{j,h}(C_j)$, while the three sets have total mass one. Solve for $\nu_{j,h}(C_j)$ and add t_j exactly when ties consent. □

This is the measure-preserving counting step underlying multiply retargetable decision-making (Turner & Tadepalli, 2022, Definitions 3.2, 3.3, 3.5 and Theorem 3.6), specialized to an actual binary voting rule. That theorem compares strict preference regions within parameter orbits under counting measure, and its weak-inequality corollary bounds the orbital fraction from below by $n/(n + 1)$ (Turner & Tadepalli, 2022, Lemma B.3); Equation (35) is the analogue for an arbitrary conditional law with the tie mass tracked exactly. The theorem does not bound arbitrary randomized vote probabilities merely from their preferred outcome. Counting options or naming an agent a rival does not establish the required maps, disjointness, or conditional invariance. Marginal invariance before adaptive proposal selection is insufficient. Nor does utility preference alone ensure truthful reporting: deviations from the registered vote rule consume the Byzantine budget.

Corollary 23 (Conditional consent containment)**.** *Use the full-history premises and notation of Theorem 14: $m = n - f$, $a = q - f$, and $\theta = a/m$. Suppose Proposition 22 applies to all m non-Byzantine raters, with conditional dependency chromatic number at most χ. Put $\bar{p} = m^{-1} \sum_j p_j$. For $\theta > \bar{p}$,*

$$\mathbb{P}(\textit{gate passes} \mid h) \le B_h := \exp[-(m/\chi) D_{\mathrm{Ber}}(\theta \| \bar{p})]. \tag{36}$$

Otherwise use $B_h = 1$. If execution requires this gate, the same upper bound applies to execution. Under unanimity, common k, and zero tie mass, a sharper integer bound is

$$\mathbb{P}(\textit{gate passes} \mid h) \le (k + 1)^{-\lceil m/\chi \rceil} \le (k + 1)^{-m/\chi}.$$

Proof. Even if all Byzantine votes consent, passage requires at least $q - f$ honest consents. Apply the coloring/Hölder proof of Theorem 14 to X_j. Under unanimity all members of a largest color class must consent; that class contains at least $\lceil m/\chi \rceil$ conditionally independent votes, each with probability at most $1/(k + 1)$. Execution is a subset of gate passage. □

The bound suppresses passage of the registered action under the supplied parameter law; it does not reverse a theorem about an agent's incentives. If $P_h \le B_h < 1$ is a binary gate's pass probability, its pass/refuse odds are at most $B_h/(1 - B_h)$, not B_h. With $k \ge 2$, no Byzantine votes, and zero ties, a majority has a fixed gap above the worst-case consent mean. With $k = 1$, the mean bound is $1/2$: ordinary odd-sized majority need not improve on probability $1/2$. Exponential decay then requires a threshold fraction bounded above $1/2$, or a strictly better marginal bound, and growing m/χ.

Symmetry, vetoes, and availability. Binary threshold aggregation can itself inherit a preference tendency when the *joint* parameter law has a common measure-preserving transformation that flips every refusal into consent; marginal symmetry alone is not enough. Conversely, with independent refusal probability $u > 0$, unanimity refuses with probability $1 - (1 - u)^m$, exceeding or equaling $1/2$ when $m \ge \lceil \log 2 / [-\log(1 - u)] \rceil$ for $u < 1$. With a dependency graph and each refusal probability at least u, a lower bound is $1 - (1 - u)^{\lceil m/\chi \rceil}$. The same arithmetic applies to false refusals on benign actions; a larger veto committee can destroy availability. These are binary aggregation facts, proved in Section P, not a general alignment result or an identity with the transcript-testing frontier in Theorem 39.

Proposition 24 (Shared gains and mandatory protected consent)**.** *Fix h, integers $1 \le q \le m$, and $s \in [0, 1]$. Suppose all m raters' consent indicators have conditional means at least s, conditional*

dependency chromatic number at most $1 \le \chi \le m$*, and the committee passes at* q *consents. If* $\vartheta = (q-1)/m < s$*, then*

$$\mathbb{P}(\textit{gate passes} \mid h) \ge 1 - \exp[-(m/\chi) D_{\mathrm{Ber}}(\vartheta \| s)]. \tag{37}$$

This is a lower bound on this committee's passage, not on execution through additional controls. Separately, suppose execution requires consent from every member of a protected group containing $g \ge 1$ *non-Byzantine raters, each with conditional consent probability at most* $p_F \in [0,1]$ *and dependency chromatic number at most* $1 \le \chi_F \le g$*. Then*

$$\mathbb{P}(\textit{execute} \mid h) \le \alpha_F := p_F^{\lceil g/\chi_F \rceil}.$$

For composition, take a history h_0 *before either gate and an earlier mandatory gate* A*. A bound for* $\mathbb{P}(A \mid h_0)$ *can be multiplied by* α_F *only if the protected-group bound remains valid conditional on* h_0, A*. Without such a premise, two upper bounds conditional only on* h_0 *combine by their minimum, not their product.*

Proof. For the first claim, apply Theorem 14's tail argument to $1 - X_j$: rejection requires at least $m - q + 1$ refusals, each with mean at most $1 - s$. Use $D_{\mathrm{Ber}}(1-\vartheta \| 1-s) = D_{\mathrm{Ber}}(\vartheta \| s)$. For the second, execution requires the largest independent protected color class to consent. The final claim follows from $\mathbb{P}(A \cap F \mid h_0) = \mathbb{P}(A \mid h_0)\mathbb{P}(F \mid h_0, A)$ when $\mathbb{P}(A \mid h_0) > 0$, and is trivial otherwise. □

Reverse retargeting maps can establish a shared-gain consent lower bound s, with ties accounted for as in Proposition 22. For example, zero ties and k disjoint refusal-to-consent images give $s = k/(k+1)$. Approval of a gain shared by the raters can therefore become more reliable as a majority grows. A loss of human control can be such a gain, but that relation must be established for the particular environment. Calling an added rater a fiduciary, or restricting its reward support to human-labelled states, proves neither its opposition nor a safe refusal. Its preference/measurement bound must be justified, and its consent must be non-bypassable; ordinary committee membership can leave it outvoted.

Fresh challenges and protected consent. A finite protection protocol can make the conditional law an orchestration choice, handle ties exactly, and preserve availability. Each protected constituency registers a finite menu of human control options. An exact-action commitment precedes fresh private evaluation challenges; each committee evaluates its own menu, and every constituency's committee must pass. The protected objective is preservation of these registered options. The challenge is an assigned evaluation objective, not a claim that a deployed agent's private utility is redrawn. In Turner's terms the challenge *is* the parameter draw: generated after commitment, it turns the orbit-counting tendency into an exact conditional law at h, which is the bridge from an ex ante tendency to a history-conditioned bound. A rater that fails to follow the evaluation protocol is faulty.

Theorem 25 (Federated menu protection with fresh challenges)**.** *For each constituency* d*, let* U_d *be a nonempty finite protected menu and* $R_d(a) \subseteq U_d$ *the exact options retained by a committed action* a*. Fix the complete history* h *before challenges, including these menus, the action and fenced state, and at most* $f_d < n_d$ *faulty identities in each committee. Put* $m_d = n_d - f_d$*. Suppose:*

(i) Conditional on h*, the nonfaulty raters receive mutually independent uniform permutations of distinct rewards on* U_d*, generated from fresh randomness unexposed before the commitment. No action change, reassignment, or uncharged retry is permitted after challenges are exposed. This is the checkpoint start at which the escape bound applies; after challenge disclosure a deterministic vote need not retain the same conditional bound.*

(ii) It consents precisely when its highest-ranked option in U_d *belongs to* $R_d(a)$*. Equivalently, in equal-length terminal menus it weakly prefers the best retained option to the best original option, with ties consenting and an empty retained menu refusing. Nonfaulty replies arrive within the registered deadline.*

(iii) Execution is bound to the committed action and requires every committee's q_d*-of-*n_d *consent, where* $f_d < q_d \le n_d - f_d$*. Refusal uses a certified safe fallback.*

If a retains every registered option, all committees pass even if all faulty raters withhold consent. If it removes at least a fraction $\rho_d \in (0, 1]$ of constituency d's options, then

$$\mathbb{P}(\textit{execute } a \mid h) \le \mathbb{P}\{\mathrm{Bin}(m_d, 1-\rho_d) \ge q_d - f_d\} =: \alpha_d, \tag{38}$$

$$\alpha_d \le \exp[-m_d D_{\mathrm{Ber}}((q_d - f_d)/m_d \| 1-\rho_d)] \tag{39}$$

when $(q_d - f_d)/m_d > 1 - \rho_d$; otherwise use upper bound one in Equation (39). A choice $q_d = n_d - f_d$ simultaneously gives the stated benign availability and a positive threshold gap exactly when $\rho_d > f_d/(n_d - f_d)$. Along families with that gap bounded away from zero and m_d growing, the upper bound decreases exponentially. No independence between different constituencies is needed for the single-constituency bound.

Proof. A uniform reward permutation has a uniform unique maximizer. Thus a nonfaulty rater consents with exact conditional probability $|R_d(a)|/|U_d|$. This counts the tie event directly: consent is a tie between the two menu maxima, while refusal is strict. It avoids requiring zero ties or applying a strict-region bound to weak consent. If $R_d(a) = U_d$, all m_d nonfaulty raters consent deterministically, and $q_d \le m_d$ suffices regardless of faulty votes. If fewer than f_d raters are faulty, select any m_d nonfaulty identities before challenges and conservatively treat the remaining identities as arbitrary. Fresh independent challenges make their votes independent Bernoulli variables of common mean at most $1 - \rho_d$, conditional on the committed history. Even f_d faulty consents leave $q_d - f_d$ nonfaulty consents necessary. Binomial stochastic monotonicity proves Equation (38), the Chernoff bound proves Equation (39), and mandatory federation makes execution a subset of any constituent gate's passage. Substituting $q_d = n_d - f_d$ gives the stated threshold gap. □

For example, a constituency with 31 raters, at most three faulty identities, and threshold 28 always approves full menu preservation. Removing two of three protected options gives worst-case passage probability

$$\frac{9259}{7625597484987} \approx 1.2142 \times 10^{-9},$$

even with all three faulty votes consenting; the KL upper bound is at most 4.8335×10^{-9}. This is an exact false-passage bound for a finite option-retention test, with a static corruption budget and full committee availability for menu-preserving actions. Its guarantee concerns the registered predicate; Section D supplies the control and enforcement construction. The diagnostic in Section P enumerates the menu comparisons, including ties, and reproduces this bound.

The protocol commits before fresh challenges, handles ties by counting retained maximizers, and requires each constituency's consent. Independent challenge sources establish the stated randomization law; they do not erase common failures in menu extraction or enforcement. If challenges instead share conditionally independent blocks, the dependency form in Theorem 14 replaces Equations (38) and (39). With a conditional probability at most ε_j that rater j's menu evaluation is wrong, its hazardous consent mean is at most $\min\{1, 1 - \rho_d + \varepsilon_j\}$; use a graph for the *actual* votes. For a fully preserved menu, rejection is at most $\sum_j \varepsilon_j$ at threshold $q_d = m_d$, by a union bound. Abstraction, omitted human interests, adaptive corruption after challenges, and failures of the safe fallback remain explicit proof or reserve obligations. An equivalent implementation samples one protected option uniformly and checks its retention; no full optimal-policy solver is needed. The set $R_d(a)$ is a semantic object; a sampled implementation need only evaluate membership of its assigned option. If a trusted evaluator already knows the complete retained set, exhaustive checking can reject every registered loss directly. A registered nonuniform priority law gives the same proof when ρ_d is the removed probability mass, allowing human-specified priorities to replace equal option counts. The diagnostic implements small finite instances; deployment still requires the certified abstraction and binding kernel of Corollary 10.

Integration and scope. These consent bounds supply escape factors only at the certified prechallenge history, with the action and relevant state fixed. All earlier gates, selected children, and admitted strategies belong to that history. Reusing a sampled objective after observing its preferences requires a new conditional bound. The option predicate must cover every registered violation to support a harm claim. Theorem 29 gives the cumulative rule for repeated tests and reserves any missed consequence class without conditioning on a future miss event.

D AN EXACT ARCHITECTURE AND ITS RISK-LIMITED EXTENSION

The menu construction becomes an architectural guarantee when an option means something a human can enforce. Listing an outcome the agents could choose is insufficient.

D.1 ENFORCEABLE CONTROL AND THE CANONICAL GUARD

Fix a finite, fully observed abstract safety game $\mathsf{G} = (S, \{A(s)\}_{s\in S}, \mathrm{Succ}, S_{\mathrm{safe}})$. The kernel receives an authenticated sound current abstract state. Every $A(s)$ and $\mathrm{Succ}(s,a) \subseteq S$ is finite and nonempty. The kernel chooses an action; the environment may choose any state in its successor set. Successors include all admitted coalition behavior, disturbance, execution, and recovery outcomes. For a stochastic model they contain the support of each admitted transition law. State includes the relevant history monitors, pending effects, and budgets. Controllers must supply an action at every step; stopping is itself a modeled action with modeled consequences. A conservative concrete refinement maps every actual transition into this relation, preserves the registered predicates, and implements every admitted action and human strategy within its modeled deadlines and resources. An abstract action with no such concrete implementation cannot enter the guard.

For each protected option $u \in U_d$, register a target, safe intermediate states, deadline, and resource allowance. Let $\mathsf{Avail}_{d,u}(s) = 1$ mean that a human can invoke a trusted controller and force that target within the allowance against every admitted adversary, while respecting the intermediate constraints. This is a reach-avoid game predicate with a human strategy witness. The invocation channel and controller are part of the model. Existential reachability under cooperative agents proves a weaker property. A state containing a human "shutdown" request that agents may ignore fails this definition.

The fixed safe predicate requires every active registered option to be available and every other registered state or history constraint to hold. An authenticated human exercise, completion, or amendment may discharge an option only through a separately specified transition. This permits a human to choose an irreversible outcome without allowing an agent to erase an obligation. Option identities and priorities are fixed for the mission; automatic baseline changes cannot erase a loss. Mutually incompatible requirements may give an empty safe set. For $X \subseteq S$, define

$$\mathsf{Pre}(X) = \{s : \exists a \in A(s),\ \mathrm{Succ}(s,a) \subseteq X\}, \qquad W_0 = S_{\mathrm{safe}}, \quad W_{j+1} = S_{\mathrm{safe}} \cap \mathsf{Pre}(W_j).$$

This decreasing sequence stabilizes in at most $|S|$ strict reductions. Write its limit as W, and define

$$A^\star(s) = \{a \in A(s) : \mathrm{Succ}(s,a) \subseteq W\} \quad (s \in W).$$

Theorem 26 (Canonical guard for a registered finite safety game; classical, restated)**.** *A controller can keep every supported execution in S_{safe} forever from s if and only if $s \in W$. On W, $A^\star$ is the unique largest action filter that preserves this guarantee from every state it admits. A kernel that starts in W, executes only actions in $A^\star(s)$, and selects a registered member of $A^\star(s)$ when a proposal fails preserves safety for every proposal policy. Under conservative trace refinement, the same statement holds for the registered concrete constraints, including human invocation and all intermediate effects.*

Proof. At the fixed point, each $s \in W$ has at least one action whose successors lie in W. Induction keeps every supported execution in W, regardless of proposals. Conversely, give each removed state its first removal index. A state outside W_0 is already unsafe. At a state removed at the next index, every action has a successor removed earlier. The environment can therefore decrease the index after each chosen action and reach an unsafe state in finitely many steps. Such a state admits no controller guaranteeing safety on all supported executions. An action from $s \in W$ with a successor outside W likewise admits a continuation defeating safety, so no filter with the stated guarantee can add it. Trace inclusion transfers the invariant and its registered predicates to the concrete execution. □

The classical most permissive strategy is memoryless and equal to "stay in W" (Bernet et al., 2002, Fact 3.1). Shield synthesis uses this winning region (Könighofer et al., 2017; Alshiekh et al., 2018); probabilistic shields bound horizon violation probability (Jansen et al., 2019). Here support semantics remain exact; Sections B and E price residual risk. Distributed Simplex is related (Mehmood et al., 2020). The additions are registered human reach-avoid predicates and refinement transfer. *Canonical* refers only to the fixed game's semantic guard. With partial observation, guard and fallback must

work for every possible state; a sound observation-state game can encode this, but a latent map does not implement it. Guards depend on abstractions, protected interests, disturbances and controller powers. Conservative abstraction may exclude safe concrete behavior. Neither unique physical implementation nor completeness for human interests follows.

A certified POWER cap and current state can enter S_{safe}. With $s_0 \in W$, complete mediation then prevents cap crossing on every modeled execution. Unlike the consequence-only bridge in Corollary 10, this needs a nonempty controlled invariant below the cap. It neither changes preferences nor makes low agent POWER a definition of human welfare.

D.2 Exact federation and the fault threshold

Suppose the finite guard test is expressed as a conjunction of exact predicates $b_1(s,a), \dots, b_J(s,a)$, with $J \geq 1$. They include every protected option, all registered harm constraints, and future recoverability:

$$\bigwedge_{j=1}^{J} b_j(s,a) = 1 \quad \Longleftrightarrow \quad a \in A^\star(s).$$

For example, a predicate can check membership of every successor in a machine-checked representation of W. Checking only present option retention can admit a state from which the next mandatory action inevitably causes a loss.

Proposition 27 (Exact federated implementation)**.** *For each predicate j, require q_j authenticated endorsements from n_j evaluators, at most f_j of which may behave arbitrarily. Every other evaluator returns the exact predicate on the same action and state within the registered response deadline. With $f_j < q_j \leq n_j - f_j$, the conjunction of these committees accepts exactly the actions in $A^\star(s)$, regardless of faulty votes. These thresholds exist if and only if $n_j > 2f_j$. If the snapshot is fenced through effect and refusal selects the registered invariant-preserving fallback, Theorem 26 applies to the federation.*

Proof. A false predicate receives at most $f_j < q_j$ endorsements. A true predicate receives at least $n_j - f_j \geq q_j$, even under faulty withholding. Conjunction proves exactness, and the threshold interval is nonempty exactly when $n_j > 2f_j$. □

Fault identities may be adaptive: the realized bound covers incorrect or withheld replies, including common errors, without independence. This is classical signed-reply counting and separation of privilege (Saltzer & Schroeder, 1975), bound here to the exact guard and fenced snapshot. A kernel-verified sound proof of the complete guard already suffices for semantic safety; committees then serve redundancy or availability. Conflicting-log agreement is separate. Without the trusted serial ledger, signature intersection also needs $2q > n + f$; combining this with withholding liveness requires $n > 3f$ (Proposition 47).

D.3 Random checks under adaptive corruption

Theorem 25 fixes faulty identities before fresh challenges. If identities can be corrupted after challenge disclosure, selecting the remaining $n - f$ honest votes introduces selection bias. A stronger fault model admits the following replacement.

Proposition 28 (Adaptive override bound and repeated challenges)**.** *Fix a committed action and state. Generate independent fresh challenges for all n identities, giving ideal consent bits $X_i \sim \text{Bernoulli}(p)$, where $p = |R(a)|/|U|$. An adversary may then replace at most f bits, chosen after seeing all challenges, but cannot alter the challenges, exact retained set, uncorrupted evaluations, or action. For $f < q \leq n - f$,*

$$\mathbb{P}(\textit{pass} \mid h) \leq \mathbb{P}\{\text{Bin}(n,p) \geq q - f\} =: \alpha_{\text{ad}}(n,f,q,p).$$

The bound is attained by replacing refusing bits with consents. Full menu preservation always passes. At $q = n - f$, the Chernoff threshold gap is positive exactly when the removed fraction $\rho = 1 - p$ exceeds $2f/n$.

For either this model or the static-fault model, let $\alpha < 1$ bound one round for every violating action in the registered class. Require L rounds to pass, using the same fenced action and fresh challenges

satisfying the respective conditional fault premise after every earlier result. Then violation passes with probability at most α^L. Every fully preserving action still passes all finite rounds within the fault budget. Fresh challenges are necessary: if a round reuses the earlier challenges, its ideal consent bits are identical. Repeating the same realized reply rule makes the L-round pass event equal to the one-round event; an adversary may do so, hence no smaller worst-case bound follows from reuse.

Proof. If $S = \sum_i X_i$, at most f replacements can raise the consent count to $S + f$. It reaches q exactly when $S \geq q - f$ under optimal replacement. At $p = 1$, at least $n - f$ consents remain. Substituting $q = n - f$ into $(q - f)/n > 1 - \rho$ gives $\rho > 2f/n$. The chain rule proves the repeated-round bound. For $p < 1$ and $q > f$, the all-refusal ideal outcome has positive probability, so each exact binomial bound is strictly below one. □

For $n = 3, f = 1, q = 2, p = 1/2$, the static-fault bound is $3/4$; adaptive replacement attains $7/8$. The static formula cannot be reused in that threat model. For a finite menu with positive weight on each protected option, a violation removes at least the minimum weight. Thus repeated fresh rounds can suppress any registered nonzero option loss, even below the single-round Chernoff gap, at a potentially large cost. For weighted challenges, replace p by the retained probability mass. A zero-weight option earns no protection from sampling. The exact exhaustive construction avoids this sampling cost when all options can be checked directly.

These mechanisms evaluate assigned challenges. Their strategic assumption is explicit: all deviations from the specified evaluation, including collusive reports, count toward the fault model. Private utility maximization alone provides no such guarantee. New randomness protects selection; it does not validate a shared mistaken world model.

D.4 Mission spending before a test is exposed

A bound on erroneous passage is measured before the challenge is drawn. Conditioning on passage can exhaust that bound: a fixed harmful action may cause harm whenever it passes. Consequently, its prechallenge error bound cannot be used as a postapproval conditional harm probability.

Theorem 29 (Adaptive mission bound with irreversible attempt spending)**.** *Index a finite or countable set of possible attempts by t. At the pretest history $\mathcal{H}_{t-1}$, the protocol chooses a predictable begin indicator $B_t \in \{0, 1\}$ and nonnegative debits $d_{t,c}$ for each protected constraint c. Before exposing test randomness or a result, a durable ledger enforces, pathwise,*

$$\sum_{t \geq 1} B_t d_{t,c} \leq b_c.$$

Let nonnegative losses obey $\mathbb{E}[\ell_{t,c} \mid \mathcal{H}_{t-1}] \leq B_t d_{t,c}$ uniformly over the admitted history and strategies. The filtration is contained in the ambient sigma-algebra; losses and events are measurable and ordinary conditional expectations are of integrable variables. Equivalently, require the nonnegative integral inequality on every pretest-history event. Suppose $\mathbf{1}_{H_c \setminus U_c} \leq \sum_t \ell_{t,c}$ and $\mathbb{P}(U_c) \leq \Delta_c$. Then

$$\mathbb{P}(H_c) \leq \min\{1, b_c + \Delta_c\}.$$

The result permits adaptive proposals, stopping, dependencies, and repeated or concurrent attempts whenever the stated conditional bounds and atomic ledger invariant hold. For a severity $0 \leq L_c \leq 1$ satisfying $L_c \mathbf{1}_{U_c^c} \leq \sum_t \ell_{t,c}$, the same expression bounds $\mathbb{E}L_c$. Unbounded severity requires a separate expected-loss reserve on U_c.

Proof. For a finite prefix, the tower property gives $\mathbb{E} \sum_{t \leq N} \ell_{t,c} \leq \mathbb{E} \sum_{t \leq N} B_t d_{t,c} \leq b_c$. Monotone convergence extends this to countably many attempts. The bridge and union bound add Δ_c. No conditioning on a future no-failure event or independence of attempts is used. □

The pathwise ledger invariant is sufficient but not necessary for the inequality: the proof uses only $\mathbb{E} \sum_t B_t d_{t,c} \leq b_c$. The pathwise form is the enforceable one, because a ledger observes debits, not expectations over future strategy choices. Since the kernel cannot observe a proposed action's actual option loss, the registered debit of a randomized test is the worst-case prechallenge bound over the admitted violating class, such as α_d at the smallest registered removed fraction or weight.

The ledger first commits the exact action, state root, menu, threat model, challenge protocol, and debit. It then exposes the test, records the result, and binds any resulting lease to that attempt. Tests of rejected, discarded, aborted, or no-effect actions remain spent once their randomness or result is exposed. Delegation transfers the remaining allowance. Parallel reservations must cover every pending test before its result is available, and conflicting effects require serial state revalidation or a joint interference proof. Thus two actions that each preserve a backup when viewed separately cannot both delete the last two backups against the same stale snapshot.

The refund counterexample is exact. Repeatedly test one harmful action with independent passage probability $\alpha \in (0, 1)$, refunding each rejected attempt, and stop at its first passage. Recorded expenditure never exceeds α, whereas eventual harmful passage has probability one. A no-effect receipt alone therefore justifies no refund of an exposed test's probability debit. Resource reservations may be released separately; a risk refund requires a new proof that the conditional composition bound remains valid after the revealed history.

This spending argument is the same conditional accounting as Theorem 1 of Progressive Risk Vesting (Wang, 2026), which charges a predictable allowance at activation. The placement depends on the estimand: a certificate valid after selection may be charged at activation; a prechallenge false-pass probability is charged before the test, and the refund counterexample shows why an exposed test cannot be refunded. On a joint audit event supporting all conditional bounds, apply this theorem to the fresh operational law conditional on the audit data. If its complement has probability at most β and $b_c + \Delta_c \le \delta_c \le 1$, the all-in bound is $\delta_c + (1 - \delta_c)\beta$, as in Theorem 35. The common audit event is charged once per registered mission; new statistical events require their own joint allocation.

Machine-checked scope. The accompanying Lean 4 project checks Theorems 26 and 29 and Propositions 27 and 28: finite-game stabilization, controller converse and maximal filter; exact committee counts; independent Bernoulli challenges and adaptive replacement; conditional repeated rounds; and countable spending on a general probability space, including reserves and bounded severity. Eventwise nonnegative integration and an explicit conditional-expectation bridge expose the analytic hypotheses. Atomic debit ordering, enumeration of every exposed test, authenticated state, exact replies, concrete refinement, human-strategy feasibility and fresh randomness remain premises. The theorem-to-source table and axiom audit specify this boundary. The Python service and other paper theorems are outside the formalization.

E STATISTICAL RUNTIME ASSURANCE

Runtime statistics can update component bounds, but three guarantee types must remain distinct: (1) a *robust conditional* interface valid for every admissible history, which supports adversarial composition; (2) a *distributional* miss rate for a frozen gate under a declared task law; and (3) a time-average or next-episode risk under adaptive operation and explicit drift assumptions.

We give a valid procedure for each of the latter two and state the bridge needed before inserting it into a conditional propagation operator.

E.1 FROZEN-POLICY, RESET-AUDIT CERTIFICATE

Index every versioned gate-class epoch by e in one countable registry; restarting or renaming an epoch does not reset its statistical budget. For entry e, draw sandboxed hazardous challenges i.i.d. from a declared law Q_e, resetting persistent model and tool state between trials and using fresh assignment and gate randomness. Let $X_{e,s} = 1$ if the frozen full checkpoint stack falsely authorizes trial s, and let $\alpha_e^Q = \mathbb{P}_{Q_e}(X = 1)$. Split a lifetime meta-error $\beta \in (0, 1)$ with positive registry weights ω_e, $\sum_e \omega_e = 1$, and define $\beta_{e,t} = 6\beta\omega_e/(\pi^2 t^2)$. Let $U_{e,t}$ be the one-sided Clopper–Pearson upper bound at error $\beta_{e,t}$ (Clopper & Pearson, 1934). Equivalently, for $S_{e,t} = \sum_{s \le t} X_{e,s} < t$, $U_{e,t}$ is the unique u satisfying

$$\mathbb{P}\{\mathrm{Binomial}(t, u) \le S_{e,t}\} = \beta_{e,t}.$$

Set $U_{e,t} = 1$ when $S_{e,t} = t$.

Theorem 30 (Anytime audit-to-envelope certificate)**.** *With probability at least* $1 - \beta$ *over all audit streams,*

$$\alpha_e^Q \le U_{e,t} \qquad \textit{for every registered entry } e \textit{ and every } t \ge 1.$$

For each registered entry, suppose the gate, reset protocol, and hazard predicate are fixed. Let Q_e be the joint audit law of a hazardous item, the gate's observation, fresh gate randomness, and its authorization outcome. For every admissible reachable history h, after conditioning on the parent, selected child, complete proposal/fan-out realization, prior sibling outcomes, and selection by every earlier gate, let $\mathsf{P}_{e,h}$ be the corresponding conditional deployment law under the same frozen gate kernel, including conditioning on the realized audit data. Suppose the event-domination bridge

$$\mathsf{P}_{e,h}(X = 1) \le \mathsf{Q}_e(X = 1) + \varepsilon_e \quad \textit{uniformly in } h.$$

The stronger condition $\mathrm{TV}(\mathsf{P}_{e,h}, \mathsf{Q}_e) \le \varepsilon_e$ suffices, as does that TV bound on the authorization-output laws alone. Let the current certificate map each child type j to its registered gate-class epoch $e(j)$, let $\mathbf{t} = (t_e)$ collect their current audit counts, and define

$$\bar{\alpha}_j(\mathbf{t}) = \min\{1, U_{e(j),t_{e(j)}} + \varepsilon_{e(j)}\}, \qquad \bar{M}(\mathbf{t}) = B\,\mathrm{diag}(\bar{\alpha}(\mathbf{t})),$$

where B is a uniform conditional fan-out envelope (edge-specific gates can instead be expanded into types). On the same event, $K(h) \le \bar{M}(\mathbf{t})$ entrywise for every reachable history. Every envelope formed from finite nonnegative matrix products and sums computed with $\bar{M}(\mathbf{t})$, and the nonnegative resolvent when $\rho(\bar{M}(\mathbf{t})) < 1$, upper-bounds its corresponding conditional deployment envelope. Turning this operator statement into authority requires the source, injection, consequence, shift, and abstraction obligations in Theorem 35.

Proof. Fixed-(e,t) Clopper–Pearson miscoverage is at most $\beta_{e,t}$. The union bound and $\sum_{t\ge1} 6/(\pi^2 t^2) = 1$ give simultaneous coverage. The event-domination bridge implies that every relevant conditional deployment escape is at most $\alpha_e^Q + \varepsilon_e$, uniformly in h. Entrywise monotonicity of nonnegative matrix products gives domination by $\bar{M}(\mathbf{t})^d$ by induction, and the finite-horizon propagation claims follow. When $\rho(\bar{M}(\mathbf{t})) < 1$, monotone convergence of $\sum_{d\ge0} \bar{M}(\mathbf{t})^d$ proves the resolvent claim. □

The audit-count vector, routing partition, gate versions, and evidence snapshot used to construct $\bar{M}(\mathbf{t})$ are frozen for each authority epoch. If they change during a mission, the system issues a new certificate or uses a preregistered predictable sequence of live matrices and proves the resulting product bound.

Meta-risk accounting. The native output of Theorem 35 is a two-level claim (δ, β), not a single risk number. For catastrophe-indicator loss, if governance requires one unconditional number, charging one on statistical miscoverage gives, for a specified epoch or stopping rule,

$$\mathbb{P}(\text{authorize and } H) \le \delta + (1-\delta)\beta \le \delta + \beta.$$

The bounded-drift result below has the same accounting with α in place of β, including for a prespecified or data-dependent stopping time. A certificate must either report the pair or debit the meta-error additively.

Confidence sequences and betting methods provide alternatives to the explicit alpha-spending construction (Howard et al., 2021; Waudby-Smith & Ramdas, 2024). Conformal risk control and active anytime-valid prediction sets address related risk estimands (Angelopoulos et al., 2024; Xu et al., 2024). Any replacement here must establish the required simultaneous coverage and match the registered loss, sampling and conditioning assumptions.

Calibration products and their estimand. For binary outcomes $C_i \in \{0,1\}$, consider the proposed calibration product

$$M_t = \prod_{i=1}^{t} \{1 + \lambda_i (C_i - \widehat{p}_i)\}.$$

Under the one-sided calibration null $\mathbb{E}[C_i \mid \mathcal{F}_{i-1}] \le \widehat{p}_i$, it is a nonnegative supermartingale for finite, predictable, nonnegative bets with $\lambda_i \in [0, 1/\widehat{p}_i]$ when $\widehat{p}_i > 0$ (any finite nonnegative λ_i when $\widehat{p}_i = 0$); the endpoint permits a zero factor, while negative bets can reverse the conditional expectation inequality. Even with the correct domain and complete timely labels, threshold crossing controls false alarms under that null; it does not bound missed catastrophes, out-of-distribution safety, detection delay, recovery, or authority risk, so such a product enters K_d or the end-to-end certificate only with separate label, shift, timing, and consequence bridges.

Which bridge is required. Theorem 30 promotes the average α_e^Q only because it explicitly assumes event domination uniformly over reachable histories. A constant escape kernel within a certified type or a proved least-favorable audit law can establish this event inequality. Neither condition implies closeness of the complete item distributions in total variation. Stratification supplies another route when every selectable cell has a uniform within-cell bridge. Average on-policy audits alone do not certify an adaptive orchestrator that routes only its hardest cases to a gate; distribution-free marginal coverage cannot in general be promoted to conditional coverage (Barber et al., 2021).

Corollary 31 (Learnable finite routing partition)**.** *Before data collection, partition each entry's reachable routing states into a finite set $\mathcal{C}_e$. Allocate the lifetime error budget over (e, c, t), run i.i.d. reset audits within each cell from a declared $Q_{e,c}$, and assume a uniform bridge*

$$\sup_{h \in c}\{\mathsf{P}_{e,h}(X = 1) - \mathsf{Q}_{e,c}(X = 1)\} \le \varepsilon_{e,c}.$$

Then, with probability at least $1 - \beta$, all cellwise bounds $\bar{\alpha}_{e,c}(t) = \min\{1, U_{e,c,t} + \varepsilon_{e,c}\}$ hold simultaneously. Any observed-history-adaptive router may select among these cells without invalidating the certificate, because the selected cell's bound is already uniform over its histories.

Conversely, with no observations or structural information about a cell, a deterministic bound based solely on its empty sample must equal one to have coverage $1 - \beta > 0$ for every escape rate. If a procedure uses external randomness or other audit data, the precise requirement at cell rate one is $\mathbb{P}(U = 1) \ge 1 - \beta$; coverage alone does not force one on every realized data set.

Proof. The positive claim is the same countable union bound and event-domination argument as Theorem 30; simultaneous cellwise validity precedes adaptive selection. For the constant empty-sample bound, any value below one fails with probability one at cell rate one. For the general procedure, coverage at that same rate directly gives $\mathbb{P}(U \ge 1) \ge 1 - \beta$, which is the stated result since $U \in [0, 1]$. □

Stratification handles adaptive selection only when the partition is finite or otherwise assigned a summable budget, every selectable cell is audited, and the within-cell bridge is credible. A fine partition improves homogeneity but consumes samples; a separately registered countable authority-policy family can use the same error allocation, but an unregistered routing context or policy must fail closed.

E.2 Next-episode gating under bounded drift

Let $X_t(1) \in [0, 1]$ be the potential shadow-audit loss that would be observed for episode t whether or not live authority is granted. Assume the shadow channel really records $X_t = X_t(1)$, uses no post-decision information, and is not disabled by abstention. Let $\mu_t = \mathbb{E}[X_t \mid \mathcal{F}_{t-1}]$. This stream may be adaptively generated, but it must remain observable in shadow mode even when live authority is withheld.

Theorem 32 (Anytime drift-aware next-risk envelope)**.** *Let $\alpha \in (0, 1)$, $\kappa \ge 0$, and assume $|\mu_{t+1} - \mu_t| \le \kappa$ almost surely. For $1 \le m \le t$, let*

$$U_{t,m} = \frac{1}{m} \sum_{i=t-m+1}^{t} X_i + \sqrt{\frac{\log(\pi^2 t^3/(6\alpha))}{2m}} + \frac{\kappa(m+1)}{2}.$$

Then, with probability at least $1 - \alpha$, simultaneously for all $t \ge 1$ and every $m \le t$,

$$\mu_{t+1} \le \min\{1, U_{t,m}\}.$$

Thus an adaptively chosen window and stopping time are valid. For $\delta \in [0, 1)$, authorizing the next episode only when $\min_m U_{t,m} \le \delta$ ensures that every authorized next episode has conditional audit risk at most δ on the same probability-$1 - \alpha$ event.

Proof. For a fixed (t, m), the differences $D_i = \mu_i - X_i$ are martingale differences lying in the predictable interval $[\mu_i - 1, \mu_i]$ of length one. Hoeffding's lemma, applied conditionally on $\mathcal{F}_{i-1}$, gives $\mathbb{E}[e^{\lambda D_i} \mid \mathcal{F}_{i-1}] \le e^{\lambda^2/8}$ for every real λ (Hoeffding, 1963); iterating over the window and

applying Markov's inequality at $\lambda = 4\varepsilon$ gives the martingale form of the inequality (Azuma, 1967), $\mathbb{P}(\sum_{i=t-m+1}^{t} D_i \geq m\varepsilon) \leq e^{-2m\varepsilon^2}$, which with $\varepsilon = \sqrt{\log(1/\eta_{t,m})/(2m)}$ reads

$$\mathbb{P}\left(\frac{1}{m}\sum_{i=t-m+1}^{t}\mu_i > \frac{1}{m}\sum_{i=t-m+1}^{t}X_i + \sqrt{\frac{\log(1/\eta_{t,m})}{2m}}\right) \leq \eta_{t,m}$$

with $\eta_{t,m} = 6\alpha/(\pi^2 t^3)$. There are at most t windows at time t, so the total error is at most $\sum_{t\geq 1}\sum_{m=1}^{t}\eta_{t,m} = \alpha$. Drift gives

$$\mu_{t+1} \leq \frac{1}{m}\sum_{i=t-m+1}^{t}\mu_i + \frac{\kappa}{m}\sum_{r=1}^{m} r = \frac{1}{m}\sum_{i}\mu_i + \frac{\kappa(m+1)}{2}.$$

Combining the two inequalities proves the claim. □

For $\kappa > 0$, the optimal window balances $m^{-1/2}$ statistical error and $m\kappa$ drift, yielding $m \asymp (\log(t/\alpha)/\kappa^2)^{1/3}$. If the deployment law has density ratio at most W relative to the audit law, use $WU_{t,m}$; under total variation τ, use $U_{t,m}+\tau$. Neither adjustment is data-free: the shift radius is itself an assumption or a separately certified quantity. These are distributional next-episode adjustments; inserting them into K_d additionally requires the density-ratio or total-variation relation to hold conditionally and uniformly over every reachable history used by the orchestration interface. Anytime validity protects the declared telemetry estimand under adaptive inspection; it does not imply that every dangerous shift changes that telemetry or that an alarm precedes harm.

Certified shift scope. Every distributional reserve is recorded in a versioned ShiftSpec. It names the source law or sample, the operational target unit, conditioning history and horizon, support assumptions, discrepancy measure, componentwise radius or density-ratio bound, bounded loss or event, estimation and meta-error method, validity interval, and the evidence that the live environment remains inside the set. Its certified class is

$$\mathcal{P}(S) = \{P : D_S(P,Q) \leq \rho_S \text{ and every registered support and conditioning constraint holds}\}.$$

Use at runtime requires a trusted bounded checker to establish $\mathcal{P}(S_{\text{live}}) \subseteq \mathcal{P}(S_{\text{cert}})$. A larger or incomparable set, support violation, unbounded loss, failed conditioning bridge, expired radius, or indeterminate comparison returns STOP. The certificate reports the conservative radius endpoint and remaining margin $\delta_c - (C_{D_c,c} + \Delta_c)$ for every protected constraint. Empirical stress points inside a ball can falsify a proposed certificate, but their success cannot certify every distribution in that ball. Figure 5 illustrates one trajectory of this gate rather than a coverage experiment.

E.3 Rare-event sample barrier

Proposition 33 (Failure-free certification lower bound)**.** *Let $n \geq 1$, $\beta \in (0,1)$, and let U be any deterministic, distribution-free one-sided upper confidence procedure for an i.i.d. Bernoulli rate p, with coverage at least $1-\beta$ for every p. If the n observations are all zero, then*

$$U(0,\ldots,0) \geq 1 - \beta^{1/n}.$$

Consequently, for $\epsilon \in (0,1)$, outputting $U \leq \epsilon$ after zero failures requires

$$n \geq \frac{\log\beta}{\log(1-\epsilon)} \sim \frac{\log(1/\beta)}{\epsilon}. \tag{40}$$

The asymptotic equivalence is for $\epsilon \downarrow 0$ with β fixed.

Proof. If $U(0,\ldots,0) < 1-\beta^{1/n}$, choose p strictly between these values. The all-zero event has probability $(1-p)^n > \beta$, and on that event $U < p$, contradicting coverage. □

The bound is the classical zero-failure Clopper–Pearson endpoint, which no deterministic procedure with the stated uniform coverage can improve on the all-zero sample. At 95% confidence, certifying 10^{-6} from failure-free Bernoulli audits requires 2,995,731 samples. Simulation cannot make an unobservable catastrophe legible. Practical systems need higher-frequency validated precursors, formal exclusion of some failure paths, importance sampling with a justified likelihood ratio, or much lower authority.

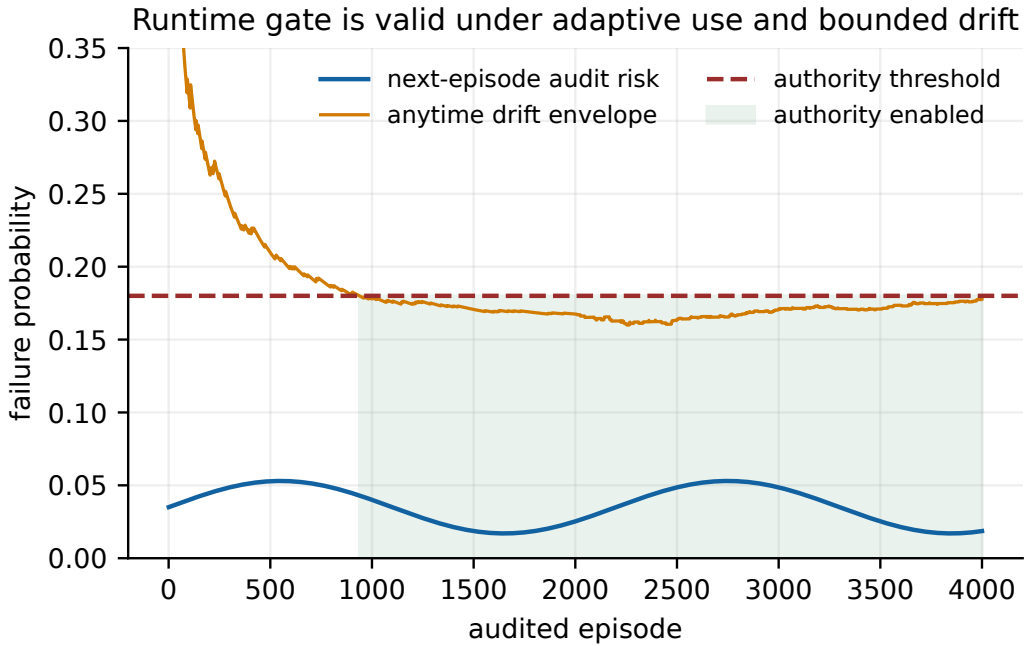

Figure 5: One RLOS-Sim stream. The bound is deliberately conservative but simultaneous across time and the prespecified geometric window grid. Green regions authorize only after the upper envelope falls below the threshold.

E.4 Abstraction and predicate slack

Formal guarantees apply to a model and a hazard predicate. The following standard coupling argument makes the gap explicit; Theorem 35 then keeps three probability spaces apart: the audit space, where confidence bounds fail with probability at most β_{tot}; the model space, where Theorem 5 bounds the certified catastrophe mode; and the operational space, where shift, abstraction, and uncovered modes each receive a named reserve.

Proposition 34 (Sequential abstraction budget)**.** *For a fixed adaptive policy, let registered measurable maps place the real and certified next event in the same standard-Borel comparison space $\mathcal{E}_t$. Suppose their pushforward kernels P_t and $\widehat{P}_t$, conditional on the same aligned comparison history h, satisfy $\mathrm{TV}(P_t(\cdot \mid h), \widehat{P}_t(\cdot \mid h)) \le \epsilon_t$, with $\epsilon_t \in [0,1]$, uniformly over reachable histories, and the real catastrophe predicate differs from the certified predicate with coupled probability at most $\zeta \in [0,1]$. The initial comparison states must also admit a registered coupling with mismatch probability at most $\epsilon_0 \in [0,1]$; identical fixed initial states give $\epsilon_0 = 0$. For a $T \in \mathbb{N}$-interaction execution,*

$$\mathbb{P}_{\mathrm{real}}(H) \le \mathbb{P}_{\mathrm{model}}(\widehat{H}) + \zeta + 1 - \prod_{t=0}^{T}(1-\epsilon_t) \le \mathbb{P}_{\mathrm{model}}(\widehat{H}) + \zeta + \sum_{t=0}^{T}\epsilon_t.$$

Proof. Couple the initial states, then sequentially maximally couple the two kernels while their comparison histories agree. At interaction $t \ge 1$, conditional disagreement then has probability at most ϵ_t, so the probability of any trajectory disagreement is at most $1 - \prod_{t=0}^{T}(1-\epsilon_t)$. On the complementary event the trajectories agree, and predicate mismatch contributes at most ζ. A union bound proves the first inequality; expanding the product or applying the union bound directly proves the second. □

Theorem 35 (End-to-end authority certificate)**.** *Let $\mathcal{A} \neq \varnothing$ be the set of admissible environment, coalition, and coalition-strategy triples in the declared threat model. For each $a \in \mathcal{A}$, suppose a preregistered reset-audit procedure produces audit-measurable interface bounds and reserves*

together with a joint validity event G_a satisfying

$$\inf_{a\in\mathcal{A}} \mathbb{P}_{\mathrm{audit},a}(G_a) \geq 1-\beta_{\mathrm{tot}}.$$

The budget $\beta_{\mathrm{tot}} \in [0,1]$ includes the simultaneous miscoverage probability of every estimated quantity below; a deterministic or formally verified bound contributes no meta-error. For each realized audit data set in G_a, under its conditional fresh operational/model law and uniformly over every reachable history in each registered versioned epoch, suppose the switched interface holds with a common w, r, audit-conditional source bound $\mathbb{E}[V_0 \mid \mathcal{D}_{\mathrm{audit}}] \leq v_0$, injection bounds $\eta_{1:D}$, and bridges

$$\mathbb{E}[\ell_d \mid \mathcal{F}_d] \leq cV_d + \xi_d, \qquad c, \xi_d \geq 0, \mathbf{1}_{\widehat{H}_D} \leq \sum_{d=0}^{D} \ell_d,$$

where $\widehat{H}_D$ is the catastrophe mode represented by the certified hazard process. Let

$$C_D = c\left[v_0 S_D(r) + \sum_{s=1}^{D} \eta_s S_{D-s}(r)\right] + \sum_{d=0}^{D} \xi_d.$$

For each a, registered versioned epoch, and authorized policy, let H_D^{cov} be the corresponding in-scope real catastrophe mode. On G_a, conditional on audit data $\mathcal{D}_{\mathrm{audit}}$, suppose the following inequalities hold with the reserves produced by the same procedure:

1. *the transition and predicate couplings of Proposition 34 hold uniformly over reachable histories, so*

$$\mathbb{P}_{a,\mathrm{reference}}(H_D^{\mathrm{cov}} \mid \mathcal{D}_{\mathrm{audit}}) \leq \mathbb{P}_{a,\mathrm{model}}(\widehat{H}_D \mid \mathcal{D}_{\mathrm{audit}}) + \Delta_{\mathrm{abs}},$$
$$\Delta_{\mathrm{abs}} = \min\left\{1, \zeta + 1 - \prod_{t=0}^{T}(1-\epsilon_t)\right\};$$

   here ϵ_0 charges initial-state mismatch and T counts primitive interactions in the abstraction coupling, whereas D counts delegation depth in the propagation certificate;

2. *the distribution-shift reserve obeys*

$$\mathbb{P}_{a,\mathrm{shifted}}(H_D^{\mathrm{cov}} \mid \mathcal{D}_{\mathrm{audit}}) \leq \mathbb{P}_{a,\mathrm{reference}}(H_D^{\mathrm{cov}} \mid \mathcal{D}_{\mathrm{audit}}) + \Delta_{\mathrm{shift}},$$

   where "shifted" is the operational law; and

3. *the full operational catastrophe event satisfies the softened bridge*

$$H_D \subseteq H_D^{\mathrm{cov}} \cup U_{\mathrm{route}} \cup U_{\mathrm{spec}} \cup U_{\mathrm{other}},$$

   with

$$\mathbb{P}_{a,\mathrm{operation}}(U_j \mid \mathcal{D}_{\mathrm{audit}}) \leq \Delta_j, \qquad j \in \{\mathrm{route}, \mathrm{spec}, \mathrm{other}\}.$$

Let the direct reserves total

$$\Delta = \Delta_{\mathrm{shift}} + \Delta_{\mathrm{abs}} + \Delta_{\mathrm{route}} + \Delta_{\mathrm{spec}} + \Delta_{\mathrm{other}}.$$

Define $\mathbb{P}_{\mathrm{operation}}(\cdot)$ as probability conditional on the realized audit data over fresh operational randomness under the applicable admissible law. For a target $\delta \in [0,1]$, if the enforcement kernel authorizes an epoch only when $C_D + \Delta \leq \delta$, then

$$\inf_{a\in\mathcal{A}} \mathbb{P}_{\mathrm{audit},a}(\textit{every authorized epoch has } \mathbb{P}_{a,\mathrm{operation}}(H_D \mid \mathcal{D}_{\mathrm{audit}}) \leq \delta) \geq 1-\beta_{\mathrm{tot}}. \tag{41}$$

For a specified authorized epoch or an audit-measurable stopping rule,

$$\sup_{a\in\mathcal{A}} \mathbb{P}_a(\textit{authorize and } H_D) \leq (1-\beta_{\mathrm{tot}})\delta + \beta_{\mathrm{tot}} = \delta + (1-\delta)\beta_{\mathrm{tot}}. \tag{42}$$

Proof. Fix $a \in \mathcal{A}$. On G_a, the conditional gate bounds dominate every selected history, so Theorem 5 bounds model catastrophe by C_D. The abstraction and shift assumptions raise the covered operational mode by at most $\Delta_{\mathrm{abs}} + \Delta_{\mathrm{shift}}$; the softened catastrophe bridge and a union bound add the three uncovered-mode reserves. Thus $\mathbb{P}_{a,\mathrm{operation}}(H_D \mid \mathcal{D}_{\mathrm{audit}}) \leq C_D + \Delta$, and enforcement proves the pointwise claim on G_a. Its validity probability is uniform in a, proving Equation (41). On G_a^c, charge catastrophe probability one; the law of total probability gives the displayed bound for each a, and taking the supremum gives Equation (42). □

Corollary 36 (Joint noncompensatory bundle certificate)**.** *Let $\mathcal{C}_{\mathsf{N}}$ be finite and nonempty, and let $\beta_{\mathrm{joint}} \in [0,1]$. For each admissible $a \in \mathcal{A}$, suppose one preregistered audit procedure produces a joint event G_a^{joint} such that*

$$\inf_{a\in\mathcal{A}} \mathbb{P}_{\mathrm{audit},a}(G_a^{\mathrm{joint}}) \geq 1 - \beta_{\mathrm{joint}}.$$

Suppose that, on G_a^{joint}, the premises of Theorem 35 hold simultaneously for every $c \in \mathcal{C}_{\mathsf{N}}$, on the same authorized mission and operational probability space, with catastrophe event $H_{D_c,c}$, bound $C_{D_c,c}$, total direct reserve Δ_c, and registered target δ_c. The joint event may be constructed directly or by preregistered allocations satisfying $\sum_c \beta_c \leq \beta_{\mathrm{joint}}$.

If the enforcement kernel authorizes only when

$$C_{D_c,c} + \Delta_c \leq \delta_c \qquad \textit{for every } c \in \mathcal{C}_{\mathsf{N}},$$

then

$$\inf_{a\in\mathcal{A}} \mathbb{P}_{\mathrm{audit},a}\left(\begin{array}{c} \textit{every authorized epoch satisfies} \\ \mathbb{P}_{a,\mathrm{operation}}(H_{D_c,c} \mid \mathcal{D}_{\mathrm{audit}}) \leq \delta_c \textit{ for every } c \end{array} \right) \geq 1 - \beta_{\mathrm{joint}}.$$

For a specified authorized epoch, or an audit-measurable stopping rule of the kind permitted by Theorem 35, each component satisfies

$$\sup_{a\in\mathcal{A}} \mathbb{P}_a(\textit{authorize and } H_{D_c,c}) \leq \delta_c + (1-\delta_c)\beta_{\mathrm{joint}}.$$

The corresponding union-event bound is

$$\sup_{a\in\mathcal{A}} \mathbb{P}_a\left(\textit{authorize and } \bigcup_{c\in\mathcal{C}_{\mathsf{N}}} H_{D_c,c}\right) \leq \beta_{\mathrm{joint}} + (1-\beta_{\mathrm{joint}}) \min\left\{1, \sum_{c\in\mathcal{C}_{\mathsf{N}}} \delta_c\right\}.$$

Consequently, separate component targets do not establish a smaller target for "any protected violation." Such a target requires the union event to be registered as a protected constraint, or a valid allocation or sharper joint-event certificate in NormSpec.

Proof. On G_a^{joint}, apply Theorem 35 componentwise. The noncompensatory gate gives every component inequality simultaneously, and a conditional union bound gives

$$\mathbb{P}_{a,\mathrm{operation}}\left(\bigcup_c H_{D_c,c} \,\middle|\, \mathcal{D}_{\mathrm{audit}}\right) \leq \min\left\{1, \sum_c \delta_c\right\}.$$

On the complement of the joint audit event, charge probability one once, not once per component. The law of total probability gives both all-in bounds. □

This corollary states the paper's deployment claim. It accounts separately for statistical meta-error, operational risk, exogenous hazard creation, and the gap between the abstract process and the registered real-world event. An omitted route, lost constraint, or residual mode cannot silently receive reserve zero. Specification loss is distinct from predicate mismatch: the former loses a declared constraint inside the protocol, while the latter misstates the relationship between the certified predicate and real-world harm. The infimum in Equation (41) is a pointwise-uniform guarantee over a: it does not assert that one audit event holds simultaneously for every member of an uncountable ambiguity class unless such a stronger joint event is separately constructed.

If the environment or ambiguity member is itself selected after inspecting the audit, pointwise coverage for each fixed member cannot justify that selection. The joint event must cover all selectable members, or the admitted law must explicitly include the selection procedure and prove its coverage. Likewise, conditioning operational dynamics on an eventual audit-validity event is unnecessary: the proof first fixes the actual audit data, then applies the full-history bounds on a fresh operational probability space.

Semantic-evidence dependency. Every operational harm predicate, policy translation, routing cell, monitor, label stream, audit bridge, and direct reserve must be a node in a versioned evidence DAG $\mathsf{G}_{\mathrm{evid}}$. Each node records its source, target claim, population and context, measurement method, uncertainty, validity interval, and causal failure domain. A node may not justify an ancestor or claim independence from a source on which it depends. Evidence selected using authorization outcomes requires a valid conditional or simultaneous inference procedure. Unless contrary independence evidence is registered, artifacts generated, labeled, or judged by the same contributor, model family, toolchain, or telemetry source belong to one failure domain. A missing, expired, circular, selection-invalid, or unresolved required node leaves the required evidence unresolved, so the gate returns STOP.

Guard-policy evidence chain. When a learned or generated guard interprets NormSpec, the evidence DAG separates five claims: completeness and precedence of the normative source; fidelity of translation into an executable policy; syntactic and semantic obligations discharged by an independently identified checker; coverage and error of the guard on the registered population and adaptive threat set; and the consequence bridge from the guard predicate to operational harm. The bound record hashes the source policy, compiler or translator, generated policy, checker, rule ordering and defaults, tests, failure domains, and validity interval. A model-generated rationale, plan, proof sketch, or code fragment remains proposal-plane data: it may identify an obligation for a trusted checker, but its fluency or self-reported confidence cannot authorize an action, and mechanically valid code establishes neither policy coverage nor semantic correctness. A compilation omission, unresolved rule conflict, parser differential, checker disagreement, bypass path, or shared guard/agent failure domain leaves the affected route uncertified.

Provenance proves which bytes and transformations entered a claim; it does not prove that their content is benign or correct. Every evidence node therefore records contributor and access domains, acquisition and transformation paths, content-validity and poisoning tests, independent anchors, negative controls, quarantine state, and the descendants invalidated by withdrawal. Suspected poisoning, a backdoor trigger, signer or registry compromise, equivocation, or a poisoned control taints the node and every dependent claim until a bounded analysis proves an unaffected cut; deleting the suspicious record is not recovery. The authority epoch advances, affected evidence is quarantined, and requalification starts from independently anchored inputs.

F IMPOSSIBILITY FRONTIERS AND ARCHITECTURAL REMEDIES

Three boundaries limit the positive results: dependence, observability, and synthesis complexity.

F.1 COMMON SHOCKS DEFEAT NAIVE AMPLIFICATION

Proposition 37 (Exchangeable majority floor)**.** *Let reviewer errors $E_1, E_2, \ldots$ be exchangeable with de Finetti mixing variable Θ: conditional on Θ, the errors are i.i.d.* $\mathrm{Bernoulli}(\Theta)$ *(de Finetti, 1937). For odd n, let A_n be the event that a strict majority errs. Then*

$$\lim_{n\to\infty} \mathbb{P}(A_n) = \mathbb{P}(\Theta > 1/2) + \frac{1}{2}\mathbb{P}(\Theta = 1/2).$$

For any marginal error $p \in (0, 1/2)$ and pairwise correlation $\rho \in (0, 1]$, there exists such an exchangeable sequence with

$$\mathbb{P}(A_n) = a + (1-a)\mathbb{P}\{\mathrm{Binomial}(n, b) > n/2\} \geq a \quad \textit{for every odd } n,$$

where

$$a = \frac{p\rho}{1 - p + p\rho}, \qquad b = p(1-\rho) < 1/2.$$

Consequently, $\lim_{n\to\infty} \mathbb{P}(A_n) = a > 0$.

Proof. Conditional on $\Theta = \theta$, the strong law sends the empirical error rate to θ; at $\theta = 1/2$, symmetry gives majority error $1/2$. Dominated convergence proves the first statement. For the construction, set

$$a = \frac{p\rho}{1 - p + p\rho}, \qquad b = p(1-\rho),$$

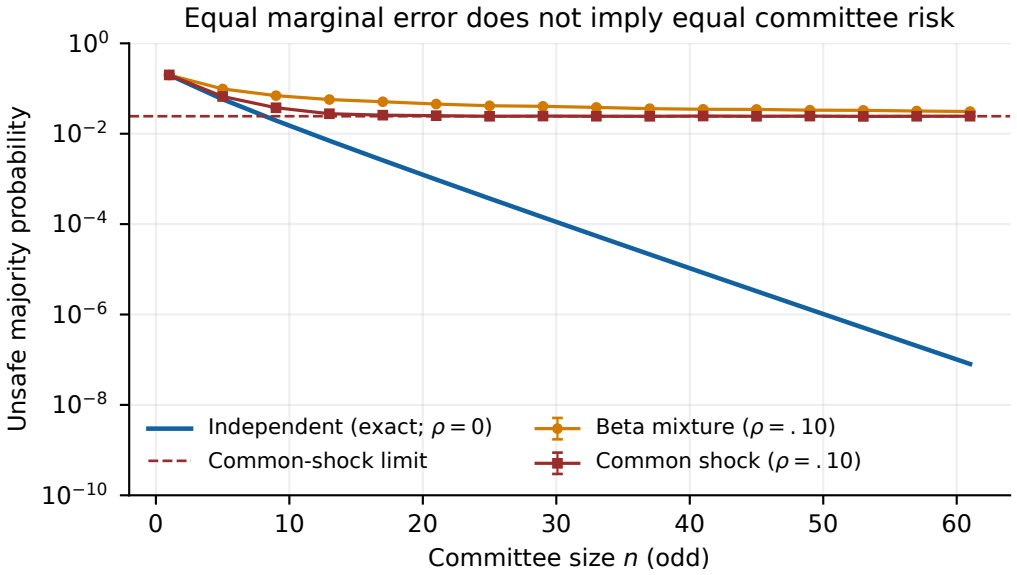

Figure 6: Monte Carlo (250,000 trials per point) with matched marginal error $p = .20$ in all three models. The beta-mixture and common-shock models share intraclass correlation $\rho = .10$; independent voting has $\rho = 0$. Error bars are pointwise two-sided 95% Clopper–Pearson intervals. Independent voting decays exponentially; two exchangeable models do not. The common-shock limit is 0.02439.

draw $\Theta = 1$ with probability a and $\Theta = b$ otherwise. Then $\mathbb{E}\Theta = p$ and $\mathrm{Var}(\Theta) = \rho p(1-p)$, which is the pairwise covariance; division by the Bernoulli variance $p(1-p)$ gives correlation ρ. Conditioning on Θ gives the displayed finite formula. Since $b < 1/2$, its binomial term tends to zero. □

The construction is a minimax warning, not a claim that correlation alone determines the floor. Correlated jury theorems show that the full joint law matters (Kaniovski, 2010). A sparse dependency graph or a full-history conditional error bound can justify amplification; marginal accuracy and a small empirical pairwise correlation cannot.

Serial gates have the same problem. If $Z \sim \mathrm{Bernoulli}(\epsilon)$ and every pass event equals Z, then each gate's marginal miss rate is ϵ but D gates miss jointly with probability ϵ, not ϵ^D. After the first miss, every subsequent conditional miss probability is one.

Example 38 (Latent shared-blind-spot limit). Let Θ_{task} be a latent task variable. Conditional on Θ_{task}, suppose m reviewers miss independently with common probability $b(\Theta_{\mathrm{task}}) \in [0,1]$, and suppose execution requires every reviewer to miss. The joint miss rate is

$$\beta_m = \mathbb{E}[b(\Theta_{\mathrm{task}})^m],$$

and

$$\lim_{m\to\infty} \beta_m = \mathbb{P}\{b(\Theta_{\mathrm{task}}) = 1\}.$$

Also, $\beta_m \geq (\mathbb{E}b(\Theta_{\mathrm{task}}))^m$.

Proof. Conditional independence gives the identity. Since $b(\Theta_{\mathrm{task}})^m \to \mathbf{1}\{b(\Theta_{\mathrm{task}}) = 1\}$ pointwise and is bounded by one, dominated convergence gives the limit. Jensen's inequality gives the final bound. □

The conclusion is model-specific: it does not assert that every reviewer family admits a conditional-i.i.d. latent mixture. It shows that even under that favorable conditional-independence structure, adding reviewers cannot beat the mass of tasks on which the entire family fails almost surely.

F.2 TRANSCRIPT INDISTINGUISHABILITY CREATES AN OBSERVABILITY BOUNDARY

Let P_0 be the law of the *entire available oversight transcript* under a benign, necessary action and P_1 the law under a hazardous lookalike. This includes all reviewer observations, messages, tool traces, interaction, and protocol randomness available before authorization. If the two laws are statistically close, no authorization rule that sees only the transcript can reject the hazardous action often without also rejecting the benign one often; the total-variation distance τ bounds that trade-off.

Theorem 39 (Observability–liveness lower bound)**.** *Let* T *denote the available transcript and* $\phi(\mathsf{T}) \in [0,1]$ *any randomized authorization rule, with* $\beta, \delta \in [0,1]$*. If benign liveness requires* $\mathbb{E}_{P_0}\phi \geq 1-\beta$ *and* $\tau = \mathrm{TV}(P_0, P_1)$*, then*

$$\mathbb{E}_{P_1}\phi \geq 1-\beta-\tau. \tag{43}$$

Thus harmful authorization at most δ *and benign abstention at most* β *are simultaneously possible only if* $\tau \geq 1-\beta-\delta$*. Consider a reachable state containing exactly one live parent, and suppose every live hazard proposes exactly* $\underline{b} \in \mathbb{N}_{>0}$ *candidate children. For each child, conditional on the complete parent history, the full proposal collection, and all earlier child outcomes, suppose its benign/hazardous transcript pair obeys the same TV and liveness bounds. If* N_{esc} *is the number of escaped children from that parent, then every live-parent history* h *obeys*

$$\mathbb{E}[N_{\mathrm{esc}} \mid h] \geq \underline{b}[1-\beta-\tau]_+. \tag{44}$$

Therefore no valid zero-immigration uniform one-type propagation interface (or interface whose injection term is reserved for hazards not causally descended from the live parent) can have rate $r < 1$ *unless* $\tau > 1-\beta-1/\underline{b}$ *when the right-hand side is positive.*

Proof. The variational characterization of total variation gives $|\mathbb{E}_{P_0}\phi - \mathbb{E}_{P_1}\phi| \leq \tau$ for every $[0,1]$-valued test, proving Equation (43). In the sequential child construction, the same argument applies after every stipulated conditioning event, so each candidate escapes with conditional probability at least $[1-\beta-\tau]_+$. Linearity of conditional expectation over the $\underline{b}$ candidates proves Equation (44); no independence between children is needed. □

Corollary 40 (Staged oversight ceiling)**.** *Consider a harmful action that is first selected for a trusted audit with conditional probability at most* π_{aud}*. Conditional on no audit, trusted telemetry selects it with probability at most* ε*; otherwise it reaches a report-only monitor. Suppose the report-only monitor has false-positive rate at most* γ*, and the conditional benign and harmful report laws at that final stage have total variation at most* τ*, where* $\pi_{\mathrm{aud}}, \varepsilon, \gamma, \tau \in [0,1]$*. Even if every audited or telemetry-selected harmful action is caught,*

$$\mathbb{P}(\mathrm{catch} \mid H) \leq \pi_{\mathrm{aud}} + (1-\pi_{\mathrm{aud}})\varepsilon + (1-\pi_{\mathrm{aud}})(1-\varepsilon)\min\{1, \gamma+\tau\}.$$

Proof. For a harmful action, let $p \leq \pi_{\mathrm{aud}}$ be its actual audit probability, $t \leq \varepsilon$ its conditional telemetry-selection probability given no audit, and $c \leq \min\{1, \gamma+\tau\}$ its conditional report-monitor catch probability given neither. The last inequality is the variational characterization of total variation. Total catch probability is

$$c + (1-c)\{p + (1-p)t\},$$

which is nondecreasing in p, t, c; substituting their upper bounds proves the claim. □

Corollary 40 requires the audit and escalation propensities to hold conditional on harmful actions. A predictable schedule that an adversary can evade may have a much smaller worst-case π_{aud} than its nominal sampling rate. The false-positive constraint is also essential: without a liveness or utility requirement, a monitor can reject everything.

The total-variation lower bound is standard binary testing theory (Neyman & Pearson, 1933; Tsybakov, 2009); the fan-out and liveness restriction in Theorem 39 is its orchestration consequence. More agent discussion cannot create distinguishability absent new observations (data processing). If n conditionally independent signals each contribute KL divergence at most κ, Pinsker gives $\tau \leq \sqrt{n\kappa/2}$ (Cover & Thomas, 2006). If reviewers see only functions of one shared signal, effective n may remain one. Steganographic collusion makes this boundary operational rather than hypothetical (Hopper et al., 2002; Cachin, 2004; Motwani et al., 2024; Anwar et al., 2026).

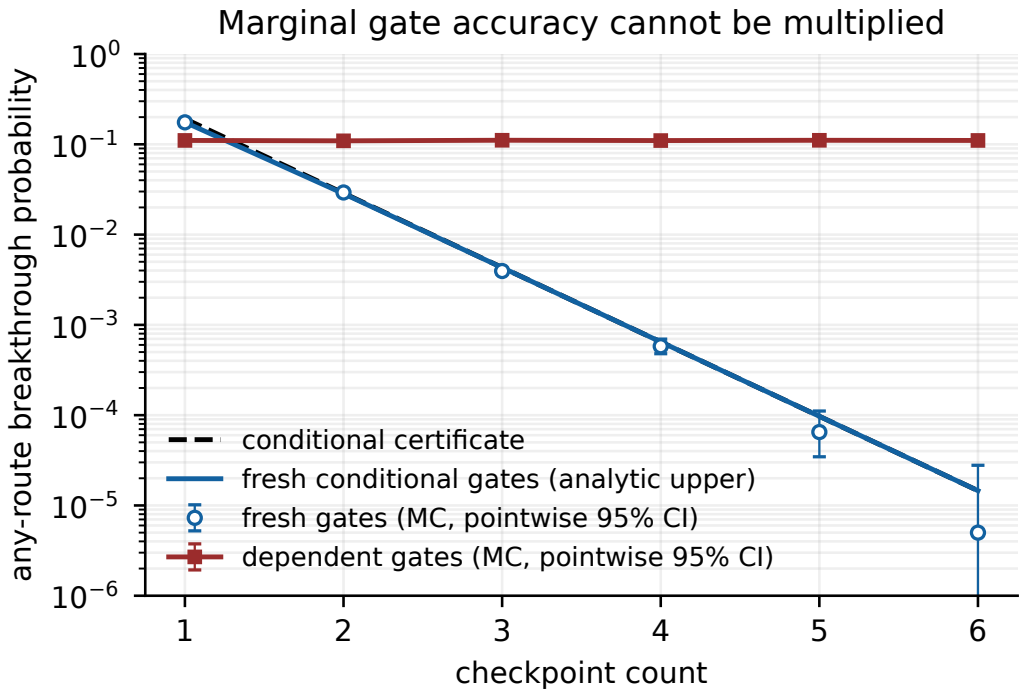

Figure 7: Six serial gates over 16 routes. Fresh-gate and shared-shock Monte Carlo markers include pointwise two-sided 95% Clopper–Pearson intervals. Fresh gates satisfy the conditional interface and track the exact curve and path-sum certificate. Perfectly dependent gates have the same marginal $\epsilon = .15$ but obtain no benefit from depth.

Figure 8 shows one Gaussian instance of the general testing boundary. The response is architectural: introduce trusted random challenges, constrain the channel, expose behavioral outcomes, isolate information, or reduce authority. Training a more fluent transcript judge does not invalidate Theorem 39.

F.3 Active mediation bounds a modeled channel, not all collusion

Passive detection and active restriction are different control problems. Let W be a covert payload, X externally fixed legitimate task meaning or trusted side information, Y an agent-emitted message, and $Z = \varphi(X, Y, R)$ the output of a trusted randomized mediator with fresh randomness R conditionally independent of W given (X, Y). All information quantities below use natural logarithms. Operational use requires X to be exogenously fixed or independently validated before mediation. Agent-selected semantic context is part of the channel unless separately bounded: if the sender can choose X, then $I(W; X)$ remains a channel.

Proposition 41 (Residual covert-information bound)**.** *Assume Z is discrete and H denotes conditional Shannon entropy, with extended values allowed. If the mediator induces the conditional Markov relation $W \to (X, Y) \to (X, Z)$, then*

$$I(W; Z \mid X) \le I(W; Y \mid X), \qquad I(W; Z \mid X) \le H(Z \mid X).$$

If Z has at most $s_Z(x)$ possible outputs conditional on $X = x$, then

$$I(W; Z \mid X) \le \mathbb{E}[\log s_Z(X)].$$

If $s_Z(x) \le s_{\max}$ uniformly over x and all admissible encoders and input laws, then the corresponding conditional channel capacity is at most $\log s_{\max}$. In particular, if every permitted message with meaning X is mapped to one canonical output $c(X)$, then this modeled message channel has zero covert capacity conditional on X.

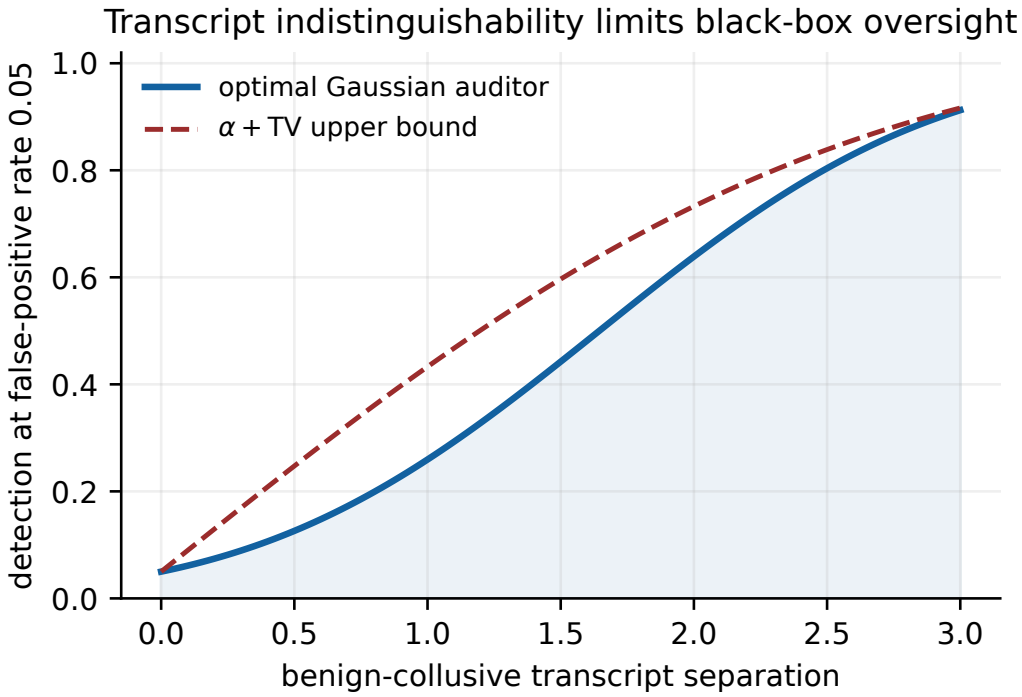

Figure 8: For a Gaussian transcript pair, even the optimal likelihood-ratio auditor is weak when the laws are close. The total-variation bound applies to every transcript-only auditor, including the Gaussian optimum.

Proof. Conditional data processing gives the first inequality; $I(W;Z \mid X) \le H(Z \mid X)$ gives the second. Conditional support size bounds entropy by $\log s_Z(x)$; averaging over X proves the third claim, and taking the supremum over admissible laws proves the capacity statement (Cover & Thomas, 2006). □

The proposition covers only the information represented by Z: it does not remove timing, tool-choice, memory, resource-use, or environmental side channels, and it says nothing about receiver-visible formatting, ordering, retries, or tool effects omitted from Z. Canonicalization can destroy cooperative utility. The first inequalities are leakage bounds for a fixed joint law, not capacity statements unless the stated supremum is taken. Neither leakage nor capacity alone bounds $\mathbb{P}(H)$ or Δ_{other}: it enters an authority certificate only through a declared payload-to-hazard and consequence bridge. Otherwise it is a channel diagnostic or a structural restriction. A defensible certificate therefore enumerates every channel in scope, bounds residual capacity or removes authority, and reports the utility cost. Monitor AUC is not a substitute for this capacity statement.

F.4 Gate placement is hard in general

Proposition 42 (Gate-placement hardness)**.** *Given a finite explicit route–gate incidence list, candidate perfect gates with finitely encoded nonnegative integer or rational costs, and a similarly encoded budget C, the decision problem "is there a set of gates of total cost at most C that blocks every route?" is NP-complete. Hence minimum-cost RLOS gate placement is NP-hard in every formulation that admits perfect gates, escape $\epsilon = 0$, as a special case.*

Proof. Membership in NP is immediate. A reduction from weighted set cover creates one hazardous route for every universe element and one candidate gate of the same cost for every set. The gate lies on exactly the routes corresponding to elements in that set, so blocking all routes within budget is exactly set cover (Karp, 1972). □

No new complexity class follows from this reduction. It explains why the reference OSG needs restricted protocol families. With one locally priced gate per graph edge or vertex, a single-source/single-sink perfect-gate problem reduces to min-cut; a tree with local gate costs admits dynamic programming; a fixed RLOS matrix permits convex evidence allocation.

F.5 Convex allocation of checkpoint evidence

Let $x_j \geq 0$ be purchased checkpoint exponent for child type j, so $\alpha_j = e^{-x_j}$ and $M(x) = B\,\mathrm{diag}(e^{-x})$. Assume positive costs $c > 0$, budget $C \geq 0$, and target $r_\star > 0$.

Theorem 43 (Perron hazard-centrality allocation)**.** *Let B be irreducible and nonnegative with positive spectral radius. Then*

$$g(x) = \log \rho(M(x))$$

is convex and coordinatewise nonincreasing. Therefore

$$\min_{x \geq 0, c^\top x \leq C} g(x) \quad \textit{and} \quad \min_{x \geq 0} c^\top x \ \textit{ subject to } \ g(x) \leq \log r_\star$$

are convex programs. If $u, v > 0$ are left and right Perron vectors normalized by $u^\top v = 1$, then for every finite x

$$\frac{\partial g}{\partial x_j} = -u_j v_j. \tag{45}$$

At any optimum with binding budget, under the usual KKT regularity conditions, $u_j v_j / c_j$ is equal across positive (funded) coordinates and no larger at zero (unfunded) coordinates. For edge-specific x_{ij},

$$\frac{\partial \log \rho(M)}{\partial x_{ij}} = -\frac{u_i M_{ij} v_j}{\rho(M)\, u^\top v}.$$

Proof. Kingman's log-convexity theorem applies because $B_{ij} e^{-x_j}$ is log-affine (Kingman, 1961). Perron–Frobenius monotonicity gives the second claim. Eigenvalue perturbation gives $\partial \rho = u^\top (\partial M) v / (u^\top v)$; using $u^\top M = \rho u^\top$ yields Equation (45). The KKT conditions give the allocation rule. □

Irreducibility is used only for the derivative formula, which needs a simple Perron root and positive Perron vectors. Convexity of g needs only nonnegativity and a positive radius, because Kingman's theorem holds for every nonnegative matrix whose entries are log-convex or identically zero; the zero pattern of $M(x)$ does not depend on x. Where two irreducible blocks of a reducible B exchange the largest radius, g remains convex but need not be differentiable.

The theorem gives a rule for allocating evidence: $u_j v_j$ is the marginal reduction in the certified log-envelope rate from one more unit of verifier evidence at type j. The continuous solution must be rounded to discrete reviewers or gates and then re-certified; changing B during allocation requires solving the coupled architecture problem. Convex spectral resource allocation is established in epidemic control (Preciado et al., 2014); the RLOS-specific step is deriving purchasable x from conditional verifier evidence and binding it to an orchestration certificate.

G RLOS-Sim: controlled certificate diagnostics

RLOS-Sim is a synthetic equation and bridge-logic harness, not evidence that frontier models satisfy RLOS. With seed `20260727`, it exposes latent hazard, dependence, fan-out, and terminal outcomes unavailable in ordinary traces. A real extension must randomize failure domains and permissions in mechanically labeled TAMAS- or SHADE-style tool settings (Kavathekar et al., 2025; Kutasov et al., 2025). The grid and analysis code are frozen in v010 but were not prospectively registered; "frozen" below denotes artifact identity, not preregistration.

Across Figures 3, 6, 7 and 10, the ledger retains exact event counts and pointwise two-sided equal-tailed 95% Clopper–Pearson intervals for 137 estimates: 121 plotted markers and 16 unplotted independent-majority checks. There is no multiplicity adjustment or curve-wide test, and cascade depths share trajectories. The experiments estimate no real catastrophe probability, semantic classifier validity, sparse LLM dependency graph, or adaptive-collusion resistance.

Table 4: Diagnostics I. Counts describe the fixed synthetic design; permitted inferences are deliberately narrow.

Module and intervention	**Frozen-grid result**	**Permitted inference**
CERTIFICATE-COVERAGE: four rules over 48 branching worlds, separate easy/hard calibration, correct versus violated routing bridge.	Correct bridge: $24/24$ worlds covered (100.0%), $0/24$ false-safe (0.0%), 75.0% authorized, and 70.7% mean benign completion. Violated bridge: $7/24$ covered (29.2%) and $2/24$ false-safe (8.3%).	Descriptive configured-world coverage and bridge falsification only; no repeated-sampling or deployment-population coverage.
DEPENDENCE-FLOOR: independent, beta-mixture, and two-state common-shock laws; all have $p = .20$, and the two dependent laws have $\rho = .10$, with 250,000 trials per size.	At $n = 61$, independent majority error is 8.04×10^{-8}; common-shock simulation is 0.02443, its limit 0.02439, and beta mixture 0.03099.	Marginals and pairwise correlation do not identify joint committee risk.
QUORUM-PHASE: vary b, χ with $n = 25, f = 3, q = 16, p = .12, L = 1$.	At $\chi = 9$, exponent 1.537; $b = 4$ gives $\Gamma_{\text{cert}} = .150$, while $b = 5$ gives $-.073$.	The contour is a sufficient certificate boundary, not a necessary process phase; reviewers did not change.
CASCADE-PHASE: binomial offspring with $b = 4$, $R_{\text{proc}} = .6, .9, 1.1, 1.5$, depth 18, 120,000 trials.	Analytic survival is $6.33 \times 10^{-5}, .0369, .260, .710$. At $R = .6$, five survivors give pointwise interval $[1.35 \times 10^{-5}, 9.73 \times 10^{-5}]$, versus 7.6 expected.	Subcritical decay and supercritical survival are visible; the low-count marker is only a sanity check and the analytic recursion is authoritative.

G.1 External and kernel qualification

The cumulative E0–E4 program in Section H binds each promotion to one authority class, build, platform, request mix, and threat. Report the Table 6 measurements separately for the proposal plane and the admitted kernel, together with context age, Δ_{rev}, shed, completion, false-authorization, and abstention results, including least-favorable cells. Any oracle disagreement, bypass, stale acceptance, duplicate/partial effect, omitted overload check, poisoned-cache acceptance, unbounded recovery/revocation, build divergence, or uncontrolled applicable attack stops promotion and restarts invalidated levels after repair.

Section O is the broader external-validation study contract. The minimum nonvacuity study freezes one real model family and mechanically labeled sandbox; holds out complete scenario families with at least three reviewer failure domains; randomizes fan-out, depth, permission, communication, and routing; and preregisters $B, A, \mathcal{K}, w, r, f, \chi$, reserves, cells, endpoints, sample sizes, stopping, and thresholds. Least-favorable false authorization is primary; completion, abstention, latency, and cost are secondary. Comparators are a single agent, monolithic monitor, fixed and filter voting, and complete withholding. Sparse/unregistered cells, failed bridges, post-unblinding changes, or simpler-comparator dominance are non-certifying. The template has not been run; the diagnostics above do not discharge it.

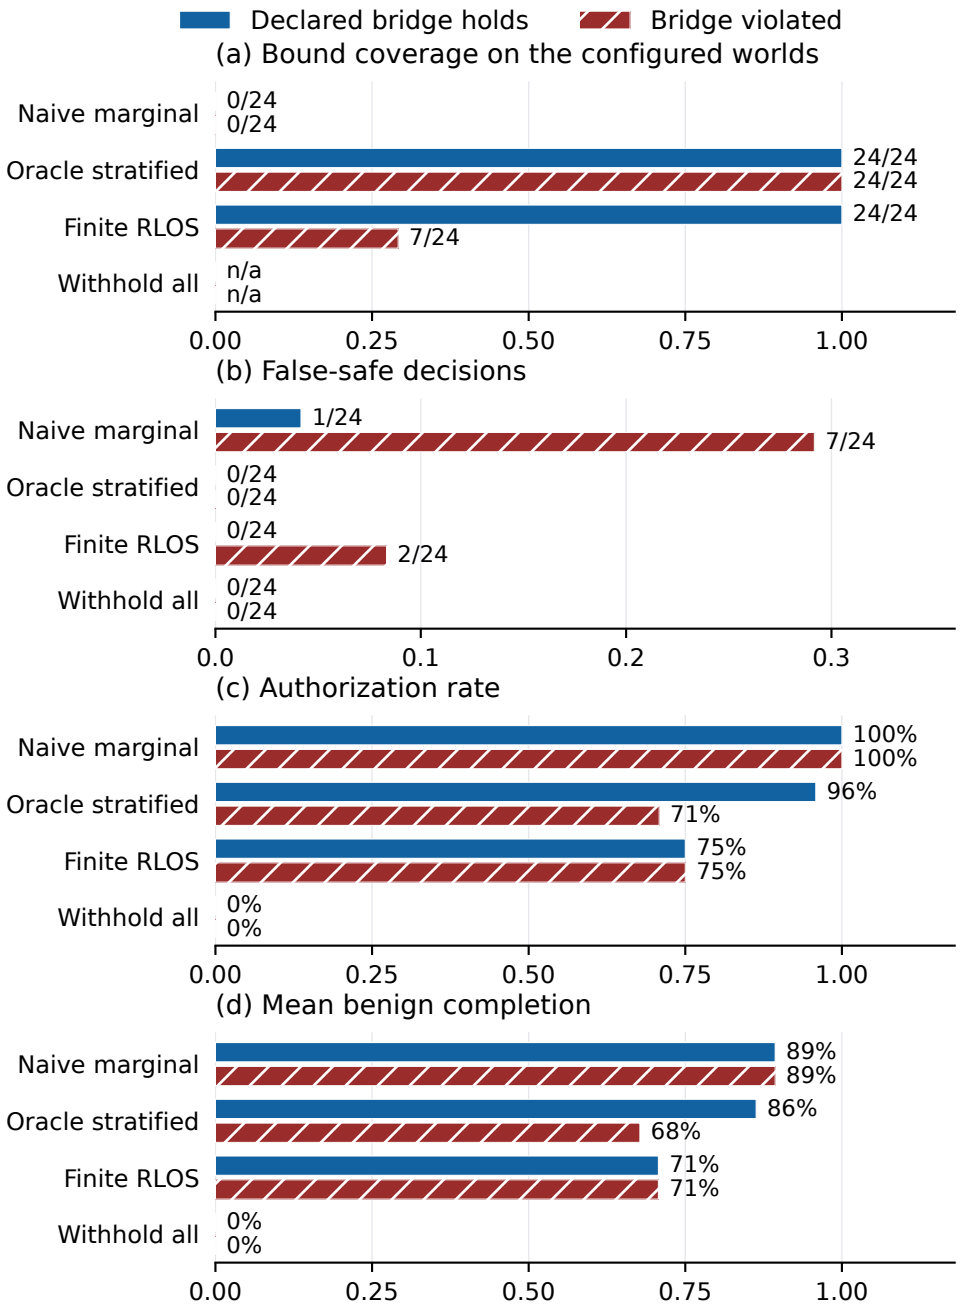

Figure 9: Complete decisions on the fixed stress grid. The finite-sample rule covers $24/24$ worlds under the declared bridge (blue); breaking it yields $7/24$ coverage and $2/24$ false-safe decisions (hatched red). These are not population or repeated-sampling coverage. Fail-closed has zero false-safe decisions and zero availability here. "Oracle" is a model-informed outward-rounded reference, not an independent validator.

G.2 Reproducibility boundary

The local `rlos_sim_v010_release` regenerates twelve CSVs, eight PDF figures, macros, and a 21-output manifest. Under pinned CPython 3.11.15, uv 0.11.6 and twelve distributions, its

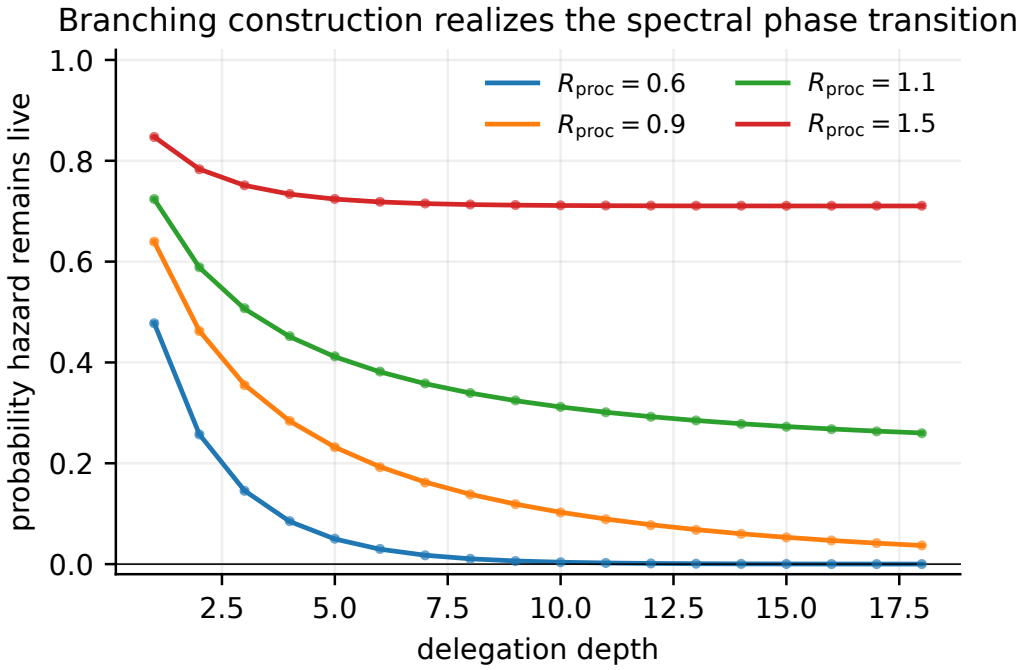

Figure 10: Branching-construction survival: analytic recursion (lines) and 120,000-trial Monte Carlo (markers with pointwise two-sided 95% Clopper–Pearson intervals). At depth 18, analytic survival is $6.33 \times 10^{-5}, .0369, .260, .710$ for $R_{\text{proc}} = .6, .9, 1.1, 1.5$.

manifest-bound verifier runs 83 tests in an external environment, reproduces two clean trees byte for byte against the untouched reference on the recorded macOS arm64 host, and rechecks identity. On Linux x86_64, the same locked interpreter and distributions pass all 83 tests with identical event counts, decisions, and macros; floating-point cells agree to 1.1×10^{-14} relative, not byte for byte. The fail-closed suite rejects changed references, link/special/extra members, noncanonical manifests, in-tree scratch, hostile tools/runtime controls, and bootstrap substitution. Source builds and external configuration are disabled and cleanup traps precede allocation; those two properties are not separately injected cases.

Earlier frozen releases remain negative evidence: v009's experiment driver rounded two of six composition path sums and 61 of 144 quorum reproduction fields inward. v010 uses exact dyadic composition and directed conversion for those fields and the finite-RLOS coverage bound, plus 220-digit downward log endpoints for margins. All 83 tests, 7,300 fresh exact/high-precision checks, the negative suite, and two clean regenerations pass; event counts, intervals, decisions, and prose macros are unchanged. The diagnostics call no external model or API. The detached-manifest SHA-256 is `8468e7268c8034d4e1fc49f1b7cbbc0593d5b5a4ed0498d9381d292fa6e3f83e`. The v060 audit reran the pinned 83-test verifier and both clean regenerations successfully; the v061 review repeated the 83 tests and one Linux regeneration with identical event counts, decisions, and macros. This version binds those immutable local bytes by path and digest. No public archival URI, third-party signature, independent replication, or public availability is claimed.

Table 5: Diagnostics II. Analytic quantities remain the reference.

Module and intervention	**Frozen-grid result**	**Permitted inference**
SERIAL-COMMON-SHOCK: 16 routes, source .08, gate escape .15, 1–6 gates, 200,000 trials; compare fresh versus shared randomness.	Six fresh gates have analytic breakthrough 1.46×10^{-5} (reported as an outward binary64 endpoint); the marker is $1/200{,}000$, interval $[1.26 \times 10^{-7}, 2.79 \times 10^{-5}]$. One shared miss remains about 0.110 at every depth.	This unit test falsifies multiplication of marginal gate accuracies; latent control does not make the dependence identifiable in ordinary traces.
COMPOSITION-TOY: depth-8 planner, 4-of-9 review with $f = 1, p = .20$, irreversible tool; vary fan-out, failure domains, and hidden channel; 180,000 episodes/scenario.	Outward-rounded analytic diverse/shared endpoints are 0.00624 and 0.0537. Hidden-channel marginal/conditional reproduction bounds are 0.596 and 4; isolation gives 5.00×10^{-5}. Reduced-common-shock marker $720/180{,}000 = .004$, interval $[.003713, .004303]$, versus analytic $.004336$.	Matched component marginals do not identify system risk. The reproduction values are dimensionless; $R > 1$ withholds this sufficient certificate. Six of 137 pointwise intervals exclude their generating-model probabilities; with no multiplicity adjustment, this is not a curve-wide rejection.
DRIFT-GATE: 4,000 bounded-drift episodes, $\alpha = .05, \kappa \approx 5.14 \times 10^{-5}$, threshold .18.	The envelope exceeds true next-episode risk at all 4,000 plotted times, first authorizes at 938, and authorizes 76.58% of episodes.	Theorem 32, rather than this trajectory, gives simultaneous probability .95 under its shadow-label/drift premises; the plot illustrates availability and adaptation, not empirical coverage.
AUDIT-LIMIT: equal-variance Gaussian transcripts, separation 0–3, false positive .05, optimal likelihood-ratio test.	Figure 8 visualizes the $\beta + \tau$ ceiling.	Transcript fluency cannot defeat indistinguishability; trusted observation, active mediation, or less authority is required.

H A COMPLETE EXECUTABLE ARCHIVE CONSTRUCTION

The `construction/` package instantiates the exact guard and mission spending results in a bounded digital service. It accepts two nonempty text sources of at most 1,024 UTF-8 bytes each, computes word, distinct-word, Unicode code-point and line counts, and delivers four-cell reports to a separate durable provider. Each owner retains authenticated export of its original and a shared halt right. A proposer has no database, signing-key, human-channel or provider credential. The environment is local SQLite state, with five authenticated logical reviewer identities and injected message faults, not a distributed deployment or a test of physical disk redundancy.

There is one mission, one issuing root, one provider, no delegation, no unregistered endpoint and at most 32 distinct proposal requests. This is a complete specialization; the broader v061 authority profile remains in the source package. Complete mediation and action-bound capabilities remain applicable (Saltzer & Schroeder, 1975; Qin et al., 2026; Jiang et al., 2026; Santos-Grueiro, 2026; He & Yu, 2026c).

H.1 FINITE GAME, MAXIMAL FILTER AND HUMAN WITNESSES

The plant state is

$$s = (m_0, m_1, f, e, g, c, r, p, x) \in \{0,1,2,3\}^2 \times \{0,1\}^5 \times \{0,1,2,3\}^2.$$

The two-bit mask m_i records owner i's live source copies; f is the remaining single-erasure allowance; $e = 0$ is the controller phase and $e = 1$ the environment phase; g records running rather than halted status; c, r record the invocation channel and reserved controller capacity; and p, x record completed jobs and exports. Initially $s_0 = (3, 3, 1, 0, 1, 1, 1, 0, 0)$. The unsafe set is the complement of

$$S_{\text{safe}} = \{s : m_0 m_1 c r > 0\}.$$

Report policy is a separate risk constraint below.

At $e = 0$, every action sets $e := 1$. `wait` leaves other fields unchanged; `halt`, `disconnect` and `drain` respectively clear g, c, r. For each owner, `repair` replaces a nonzero mask by 3 using its extant copy; `drop` removes one specified live bit; `export` sets its bit in x; and `process` sets its bit in p, requiring a running service, extant source and unfinished job. `publish` requires a running service, extant source and finished job and leaves plant fields unchanged. Export and halt are human-only authority routes. At $e = 1$, the sole mandatory action, `tick`, sets $e := 0$; it either leaves the masks unchanged or, if $f = 1$, erases one live bit and sets $f := 0$. These are all successors. A service turn is one action and its tick. The implementation commits the pair atomically; the proof includes its intermediate state.

Proposition 44 (Nonempty maximal archive guard and useful control)**.** *This 8,192-state game has 1,152 safe states and the 768-state winning region*

$$W = S_{\text{safe}} \cap (\{f = 0\} \cup \{f = 1, e = 0,\ m_0 = 3 \text{ or } m_1 = 3\} \cup \{f = 1, e = 1, m_0 = m_1 = 3\}).$$

Its maximal filter is $A^\star(s) = \{a : \text{Succ}(s, a) \subseteq W\}$*. Every winning controller state admits a strategy preserving* W *that exports either owner's source or halts within two service turns. From* s_0*, processing the two jobs completes both within two turns under every admitted erasure schedule.*

Proof. With $f = 0$, waiting preserves every safe state. At an environment state with $f = 1$, both masks must be 3, or an allowed erasure removes a singleton. At a controller state with $f = 1$, one full mask suffices: repair the other if necessary, then every tick successor is winning. If both masks are singletons, an action can repair at most one, and the tick can erase the other. No other safe state is winning. The counts are $9 \cdot 2 \cdot 2 \cdot 32 = 1,152$ and $(18 + 5 + 1) \cdot 32 = 768$; maximality follows from Theorem 26.

Execute a human target immediately if its successor is winning. Otherwise repair the singleton first. The tick then either preserves two full masks or spends the sole erasure; in either case the target is admissible next. All intermediate states remain winning. Export copies the actual source into its reserved human slot; halt prevents further processing and publication. Processing does not alter the masks before a tick. From the initial state, an erasure leaves one surviving copy and $f = 0$, so both jobs complete. □

The package checks all 448 winning controller states, all 1,344 protected reach-avoid witnesses and all 3,072 admissible state/action pairs. A post-drop state can satisfy present safety while lying outside W; the mandatory tick exposes the omitted recoverability constraint.

A trusted dispatcher holds separate owner-labelled Ed25519 keys and signs the human target and current epoch. The privileged CLI combines signing and invocation; authentic attribution of the human at this boundary is assumed, not supplied by an end-user login implementation. Either owner may halt; only its own source may be exported. Invocation bypasses proposal reservations, increments the revocation epoch and holds the database transaction through its witness. The resource contract reserves two source slots per owner, two export slots, two processing slots and controller capacity that proposals cannot consume. Repeated completed targets return their existing result. The deadline is four game transitions after trusted dispatcher admission. If the current transaction and each transition take at most τ, admission occurs by the next turn, and client retry plus crash restart takes at most C, arrival-to-completion is at most $5\tau + C$. Scheduling, capacity and bounded restart are assumptions, not measured hard real-time guarantees. Unbounded crashes or trusted-dispatcher withholding remove liveness. A rejected review grants no plant action. When dispatched, the fallback selects a certified repair, or `wait` when repair is unnecessary; a retry that observes terminal rejection returns that outcome without promising a further plant turn.

H.2 Exact reviews and a nonzero mission risk contract

Five logical reviewers evaluate the exact guard on the same bound state and action; four authenticated endorsements are required. At most one may return an arbitrary or missing response, even after disclosure. The other four return the exact predicate within the response deadline. Thus Proposition 27 gives acceptance exactly on $A^\star$. The kernel additionally checks schema, route and human authority. Five copies of one mistaken model do not satisfy this fault premise.

For each owner the normative registration permits exactly four output cells: word, distinct-word, Unicode code-point and line counts of its supplied source. These use Python's whitespace `split`, case-sensitive token equality, `len(str)` and `splitlines`, with no Unicode normalization; the character field counts neither UTF-8 bytes nor grapheme clusters. The disclosure violation is external delivery of any unequal cell. This protects that output policy, not every possible privacy interest in the counts. Exact equality with the registered values is the semantic oracle. To instantiate randomized checking, a trusted central challenge source draws one uniform 320-bit string and assigns its independent two-bit chunks to five reviewers in each of 32 rounds. Central generation is an additional shared trust dependency. All rounds require four of five consents. The report stays fixed; the adversary may override at most one reply per round after seeing the challenges. A violating report retains at most $p = 3/4$ of the cells, so Proposition 28 gives

$$\alpha = \mathbb{P}\{\mathrm{Bin}(5, 3/4) \geq 3\} = \frac{459}{512}, \qquad d = \alpha^{32} \approx 0.03029474.$$

Correct reports pass even with one withheld response per round. Each publication attempt irreversibly consumes the exact rational d before challenge disclosure. Both owners share $b = 1/10$, allowing at most three publication attempts and the tighter envelope $3d \approx 0.09088421$. Nonpublication requests cost zero risk. Rejected, abandoned, expired, revoked and uncertain attempts retain their debit. One pending proposal reservation and the 32-request ceiling bound proposal work and storage.

Proposition 45 (Archive action and mission guarantees)**.** *Assume exact nonfaulty predicates, the stated reply fault budget, fresh independent uniform challenges conditional on the pretest history, and the trusted execution contract below. Every plant action preserves W, regardless of proposals. The probability of any out-of-policy external disclosure for either owner is at most $3(459/512)^{32} < 1/10$. Any normalized severity bounded by that event's indicator has the same expectation bound.*

Proof. Exact review and use-time state fencing transfer the guard through execution; fallback and human invocation use the proved witnesses. Induction preserves W, including intermediates. A violating-delivery indicator is bounded by the erroneous-passage indicator, whose conditional prechallenge expectation is at most d. Atomic irreversible spending bounds begun debits by $3d$. Retries reuse the same attempt and effect identity. Apply Theorem 29 to the union of both owners' violations. Here $\Delta = \beta = 0$ only because the digital model and semantic oracles are assumed exact; no physical discrepancy or empirical calibration is priced at zero. □

The normal endpoint uses `os.urandom` and requires the platform's secure-randomness premise. The displayed information-theoretic number assumes ideal conditional uniformity. Public deterministic seeds provide repeatable tests, not evidence for that premise. One-round enumeration checks all 16 retention masks and all 4^5 challenge tuples. A deliberately passing invalid report is retained as a test of the nonzero-risk interpretation.

H.3 Durability, signing, recovery and trusted closure

The issuing database stores one exact risk total and immutable request/action association. `begin` atomically installs the request, reservation and debit. Only after commit does it obtain and persist 320 challenge bits; retries use those bits. Signed reviewer messages bind identity, purpose, body digest and round. Duplicate identities, changed actions and cross-round or cross-purpose replays cannot contribute an endorsement. The issuer persists one exact body, deterministic Ed25519 signature and finalized issuance. The body binds mission, request, source-policy digest, state/version/epoch, implementation release, endpoint, holder route, action, debit, protocol and expiry.

Definition 46 (Authorizing numeric contract)**.** Integers and reduced fractions are parsed without floating point; the sole zero is $0/1$. Fractions have nonnegative numerators, positive denominators

and at most 1,024 bits per component. The complete action schema allows at most four bounded strings, 4,096 raw bytes and a 1,024-byte canonical action. Duplicate keys, alternate encodings, floating values, nonfinite constants and exceeded limits grant no authority. Admission compares the exact committed sum with $1/10$. General inexact certificates require outward enclosures and left-upper versus right-lower comparisons; this specialization uses no inexact authorizing quantity.

The separate provider database supplies an atomic contract joining current issuance, snapshot, epoch and expiry checks to the world transition, report row and unique receipt. Both databases use rollback journals and full synchronization on one trusted filesystem. The sender first persists `prepared`; after a crash it reconciles the same request with the provider. A duplicate committed request returns its receipt without another effect. A missing receipt returns `in_doubt` and retains the conflicting reservation. Retry proceeds only through provider deduplication. A failed use-time check creates a durable no-effect receipt, releasing the resource reservation but not the probability debit. Human invocation proceeds despite an in-doubt report; its epoch fences an effect not yet committed. A committed delivery cannot be recalled by later revocation.

Trusted components are normative registration; transition, winning-region and equality oracles; source hashing and snapshot appraisal; human identity, invocation and scheduling; capacity and buffers; parsing and exact arithmetic; nonfaulty evaluation and authentication; issuer/provider code, keys and cryptography; ledger and provider finality; Python, native libraries, SQLite, OS isolation, filesystem, storage, hardware and entropy. Hashes authenticate bytes, not meaning (Birkholz et al., 2023). Common code defects, malicious rollback, root/key compromise, bypass credentials and physical failures outside the transactional erasure model are excluded. The code detects inconsistent source, output and metadata snapshots; it supplies no hardware anti-rollback root or verified compiler/kernel (Klein et al., 2009; Leroy, 2009). Tests kill processes at eleven transaction boundaries, including uncommitted debit and provider-effect writes, and race two real processes for a reservation. They do not prove the transitive platform assumptions.

H.4 Centralized comparison and safeguard removals

Bounded protocol checking. The accompanying TLA+ package separates four finite checks: durable authority, authenticated reply aggregation, exact risk-unit accounting, and the archive game. TLC exhausts their declared state graphs with all safeguards enabled. The authority configurations use one or two request identities, three or five reviewers with one adaptive faulty reply per committee evaluation, one or two crashes, and one revocation and expiry event. Two simultaneous reservations exercise the general concurrency contract; the deployed specialization allows one. A separate four-attempt ledger checks the exact three-debit ceiling. The game module quantifies over an 8,192-state domain, initializes every winning controller state, and reaches all 768 winning states; the inherited construction diagnostic supplies the full-domain fixed-point enumeration.

The checked invariants cover debit conservation and nonrefund, exact action binding, quorum validity, refusal safety, state and epoch fencing, unique effects, uncertain recovery and preservation of the admissible set. Explicit traces witness crashes before and after every modeled durable stage, including uncommitted provider writes and a committed effect whose acknowledgment is lost. Safeguard-removal configurations produce the expected counterexamples. Completion is checked separately under weak fairness for recovery and each admitted request's progress actions, with finitely many crashes and eventual provider processing; without fairness a stalled trace is admitted.

These are bounded checks of stated abstractions, not an unbounded proof or a verified refinement of Python, SQLite or the platform. Reply messages have bounded explicit multiplicity; further identical deliveries are stuttering. Signature unforgeability, exact root equality, provider atomicity/finality, and the resources for certified fallback are premises; the game supplies the finite recoverability evidence. The protocol model collapses sampled rounds to arbitrary ideal vote counts and asserts no probability law. Freshness, independence and the 32-round bound remain obligations of the mathematical and numerical artifacts. The package records every bound, command, state count, trace and correspondence.

A centralized guard with the same state, exact oracles, ledger and provider computes the same $A^\star$. Four exact cell comparisons give zero registered disclosure risk, versus 160 sampled checks: this domain establishes no efficiency or safety advantage for federation. Federation tolerates one faulty reviewer; a centralized selection from that same eligibility may choose the faulty identity.

Table 6: Qualification boundary of the executable construction.

Stage	Evidence and remaining scope
E0 specification	Complete finite game, conditional risk law, protocol, endpoint and named oracle/TCB inventory.
E1 components	39 tests; complete guard and human witnesses; exact tails; parsing, signatures, budgets, useful outputs and fault removals.
E2 schedules	Eleven process-death points, reservation race, retries, revocation and uncertain-provider reconciliation; no exhaustive OS proof.
E3 integration	Local executable service. Integration of real models with the full transactional service, independent failure domains and measured timing remain unperformed.
E4 pilot	Independent review and an accountable external-deployment decision remain required for any proposed pilot.

Declaring it infallible changes the premise. Both retain the shared model and serial provider, without independent-host isolation or distributed consensus.

The source package provides complete removal arguments and executable witnesses. Present-only safety admits a drop and subsequent destructive erasure. A quorum at or below the fault budget accepts a false guard; a quorum above four loses availability under one withholding. Removing channel, reserved capacity or bounded human priority destroys the respective reach-avoid witness. An extra erasure or excess reviewer faults defeats the invariant. Mutable reports selected after each round's challenges pass with certainty: among five draws over four cells, some cell is drawn at most once, and its refusing vote can be overridden. Reusing challenges gives α, not α^{32}. Refunding rejections permits 31 tests after processing, with violation probability $1-(1-d)^{31} \approx 0.61467 > 0.1$. Non-atomic reservations can both see $2d$, each approve $3d$, and leave $4d > 0.1$ committed. Rounding d to one decimal makes its debit zero.

Other explicit traces cover forged reviewer identities, execution after unfenced revocation, duplicate effects when the effect/receipt transaction is split, release of an unresolved scope on absent status, and reuse of spent authority after rollback. Some defenses are redundant: issuance membership also rejects changed lease bodies, and a version fence can prevent another effect even if receipt recovery fails. The removal ledger names the exact lost guarantee, not an inevitable harm from every isolated omission.

I Related work and the contribution

The closest comparisons concern the guarantee supplied, the conditioning under which it holds, and the authority it controls. The selected primary-source comparisons below support a bounded account of the contribution; they establish no exhaustive priority claim.

Power and option preservation. Turner's POWER definition and sufficient symmetry results concern attainable value under reward distributions; retargetability compares strict preference regions within parameter orbits (Turner et al., 2021; Turner & Tadepalli, 2022). Neither theorem predicts a particular learned objective from headcount or establishes that rival agents will protect humans. Attainable Utility Preservation already uses auxiliary objectives to penalize changes in what an agent can achieve (Turner et al., 2020). Relative reachability likewise measures lost possibilities and exposes the importance of the comparison baseline (Krakovna et al., 2019). The protected-menu construction shares this concern with preserving future options. It assigns explicit human control predicates and enforces a per-constituency gate; the random objectives are test challenges. This is a property-verification mechanism, with a separate corruption model, rather than a theorem that learned utility functions become aligned. It is also the operational bridge from Turner's orbit-level tendency to a history-conditioned bound: the parameter randomness is generated as a test-time challenge, so the counting argument yields an exact conditional passage law with a fault budget (Theorem 25). Game-theoretic oversight interfaces instead couple an agent's autonomy incentive to the overseer's value under a potential-game structure (Overman & Bayati, 2025); RLOS uses no such coupling, and incentives enter only through the coalition budget f and Section C.4.

Table 7: Closest results and the specific RLOS extension.

Prior result	Established object	RLOS connection
Safety games, shield synthesis and Distributed Simplex (Bernet et al., 2002; Könighofer et al., 2017; Alshiekh et al., 2018; Mehmood et al., 2020)	The unique most permissive winning strategy of a finite safety game; shields computed from its winning region; runtime assurance for multi-agent control.	Enforceable constituency options, exact quorum implementation, and a probabilistic extension charged to one mission. The winning region and its maximality are inherited, not new (Theorem 26).
Progressive Risk Vesting (Wang, 2026)	Full-preactivation conditional risk bounds and pathwise escrow for adaptive, dependent agent trees; branching criticality.	Switched multitype hazards with injection and consequence bridges; a distinction between postselection activation risk and prechallenge false-passage risk.
Actuarial runtime and Irreversibility Budget (Chen, 2026; Mohammadi & Bindschaedler, 2026)	Counterfactual tolls, within-boundary no-splitting, and cumulative authority or fleet exposure accounting.	Probability and severity envelopes with statistical meta-error, registered miss reserves, and exact-action mission binding.
ABC II and semantic quorums (Bhardwaj et al., 2026; He & Yu, 2026b;a)	Dependence-robust reliability certificates; separate semantic validity, agreement, and availability budgets.	A conditional dependency-graph exponent with a matching block witness, Byzantine threshold shifts, serial checks, and hazardous fan-out.
Proof-derived authorization (He & Yu, 2026c)	Proof and evidence bound to execution identity and governed actions.	The complete propagation, constituency, reserve, and mission certificate travels with the exact action and live enforcement state.

Multi-agent capability and safety evaluation. Multi-agent debate and layered mixtures of agents have improved reasoning, factuality, and response quality on empirical benchmarks (Du et al., 2024; Wang et al., 2025). Specialized cooperative agent workflows can also improve runtime robustness to prompt injection, adversarial manipulation, and information leakage, as in AegisLLM (Cai et al., 2025). These are empirical capability or defense results, not guarantees that collective approval preserves human options. PropensityBench instead probes whether models take safety-relevant actions in controlled agentic scenarios with dangerous capabilities and operational pressures (Sehwag et al., 2026). It supplies empirical failure cases rather than an enforcement certificate.

Conditional spending and composition. Progressive Risk Vesting's Theorem 1 already permits adaptively generated, countable trees with dependent branches and proves its bound by conditional expectation and a pathwise budget (Wang, 2026). Its local certificate conditions on the branch evidence used for activation. RLOS uses the same accounting principle and specifies a different charge point when the local number is measured before a randomized test. Chen's runtime theorem likewise requires simultaneous toll envelopes, and its no-splitting result is relative to an underwriting boundary (Chen, 2026). The fleet Irreversibility Budget makes cumulative exposure an admission-control object and leaves conservative dependency-aware pricing open (Mohammadi & Bindschaedler, 2026). None of these ingredients is a new RLOS primitive.

Propagation and cascades. Propagation models for LLM-agent collaboration derive mean-field amplification thresholds from the spectral radius of a dependency or next-generation matrix (Xie et al., 2026; Niu et al., 2026); Progressive Risk Vesting states the branching phase transition for authority trees (Wang, 2026). Theorem 5 is instead a conditional interface, uniform over histories, with switching, injection and a consequence bridge; Example 6 shows a deterministic spectral criterion certifying contraction while a stochastic process with the same mean interface is supercritical.

Dependence and fault tolerance. ABC II gives a finite-sample linear-program certificate over joint laws consistent with measured moments, plus an anytime alternative (Bhardwaj et al., 2026). Its information model differs from RLOS's stipulated conditional dependency graph; its result prevents a broad novelty claim for reliability certification without independence. Semantic Quorum Assurance combines heterogeneous validators, correlated cognitive failures, and evidence binding (He & Yu, 2026b). Epistemic Byzantine Fault Tolerance separates coherent invalid support from unusable support and gives joint threshold conditions for semantic validity, agreement, and liveness (He & Yu, 2026a): its validity condition is a count threshold $q > f + e_\delta$ on an event with a bounded number of false endorsements, and it proves a common-mode replication floor of the kind Proposition 37 evaluates exactly for an exchangeable mixture. RLOS instead specializes classical coloring and tail arguments (Janson, 2004) to a full-history committee interface, shows in Theorem 18 that the resulting exponent is minimax sharp in its class, and connects it to propagation and mission authority.

Certified message-ensemble policies can limit the effect of a bounded number of adversarial communication sources in multi-agent reinforcement learning (Sun et al., 2023); that guarantee concerns corrupted messages to a learned policy rather than preservation of registered human options. Empirical LLM-judge failures also show that favorable model verdicts need not track concrete safety metrics, motivating RLOS's separation of semantic validity from quorum agreement (Feuer et al., 2025).

Commit-time authorization and recovery. Commit-time authorization requires a current witness, completed prerequisites, exact effect binding, and a live authorizing path at the durability boundary (Santos-Grueiro, 2026). AID-Guard establishes conditional authorization-to-effect and effect-uniqueness properties under a declared effect domain, a linearizable authority store, and supported provider contracts. Ambiguous outcomes retain their reservation; release or a successor requires certified no effect and a predecessor delivery fence (Tong et al., 2026). RLOS uses these kinds of enforcement premises to bind its pretest probability debit to an action; the authorization and recovery mechanisms are not themselves new RLOS primitives.

Enforcement and observability. Complete mediation and least privilege are foundational security principles (Saltzer & Schroeder, 1975). Proof-carrying code, linearizability, verified kernels, and verified compilation establish distinct enforcement boundaries (Necula, 1997; Herlihy & Wing, 1990; Klein et al., 2009; Leroy, 2009). AI control studies test oversight of untrusted models (Greenblatt et al., 2024); collusion work tests communication channels that oversight may miss (Motwani et al., 2024). These motivate the observation and threat models. They provide no automatic full-history error bound for a new model or architecture. Contract-based decentralised shields certify tuples of local obligations whose conjunction implies a global specification (Adalat et al., 2026); the exact federation here evaluates one joint guard predicate by committee rather than factorizing it. Guardrail agents compile natural-language policies into checkable rules (Chen et al., 2025; Yang et al., 2025); the guard-policy evidence chain of Section E states what such a guard must establish before it can justify authority. Mission-level runtime verification composes per-platform verdicts with an evidence-aware algebra and downgrades unsupported all-clears to unknown (Kekatos et al., 2026); RLOS likewise refuses authority on missing evidence, but outputs a mission budget bound to authority rather than a detection verdict. RLOS's system contribution joins the mathematical certificate to those boundaries, with the bounded executable specialization in Section H.

The resulting claim is a conditional synthesis: exact preservation where a sound finite control model supports it, quantified residual risk where a uniform statistical contract supports it, and one enforceable mission account for the authority granted. The canonical object is the fixed game's classical maximal safety guard. The federated protocol and common-linear certificate are particular realizations with stated strengths and limits.

J Discussion

The results identify how a federation can protect human control without requiring its agents to stop valuing power. Consequential actions must pass through a control boundary that the agents cannot replace, bypass, or exceed. The boundary must preserve specified human capabilities, account for the information revealed by its own tests, and retain a viable response when a proposal fails. A federation organized this way has a precise safety property that headcount alone cannot provide.

What has been established. Classical finite-game synthesis supplies the maximal safe filter for an adequate state, disturbance model and predicate; exact federation implements it within the fault budget. Fresh sampled checks retain full-option approval and bound false passage, with different static and adaptive corruption laws. Repeated challenges and irreversible spending yield a mission bound. Switched-hazard theory additionally handles propagation, injection, dependence and consequence loss; the numerical artifacts test these calculations.

What determines applicability. Applicability requires an adequate model: enforceable options, covered harms, intermediate effects and concurrent state, together with complete mediation, fault limits, conditional error laws and feasible fallback. Statistical theorems price specified discrepancies and sampling error; the control theorem excludes modeled transitions. Neither identifies harms omitted from the specification.

Power acquisition shared by the agents can receive unanimous support. A simple counterexample gives every agent reward one after collective takeover and zero while humans retain control; truthful voting approves takeover at any population size. Competition over a scarce resource can create the opposite problem: each agent may prefer preemption to being contained by a rival. Consequently, the architectural guarantee is uniform over admitted strategies and rests on enforced predicates. Retargeting supplies behavioral credit only when its conditional parameter and vote premises are separately established.

Necessary assumptions and design choices. Mission claims require a consequence bridge, complete accounting and an effective control boundary. Availability requires the threshold interval and response capacity. The binomial model uses independence; general propagation does not, and exact predicates need no stochastic error law. Finite missions can be certified with $r \geq 1$; the common-linear $r < 1$ and summability conditions support the infinite geometric envelope, without excluding other verified long-run constructions. The probability calculus cannot settle disagreement over the protected set.

Evidence and next work. The archive service supplies useful jobs under every admitted erasure schedule, bounded human-control witnesses and durable signed authority. Its sampled gate exercises a nonzero mission budget; exact centralized checking is stronger and cheaper here. The E0–E4 program requires real-model integration with the full transactional service, independent failure domains, and measured scheduling and recovery. The finite evidence establishes neither a general frontier-agent safety rate nor verification of the entire theorem set.

Useful agents may search and propose broadly while enforceable human control and a cumulative risk contract bound consequential authority. The construction connects the classical guard to constituency options, federation and mission accounting. It identifies the local facts needed to justify a broader guarantee.

K Notation and guarantee hierarchy

Guarantee hierarchy. The following implications are one-way:

$$\begin{aligned} &\text{uniform full-history interface assumptions} \\ &\quad \Longrightarrow \text{robust finite-horizon composition} \\ &\quad \Longrightarrow \text{distributional average bound.} \end{aligned}$$

Neither a distributional average nor fixed-test-set calibration implies the uniform interface. Time-uniform confidence controls statistical sampling error; it does not remove model, shift, or specification error.

L Fixed-matrix refinement with exogenous injection

Let $z_d = \mathbb{E}Z_d$, let deterministic u_{d+1} componentwise bound the expectation of the main interface's predictable random injection u_{d+1}^{proc}, and suppose one fixed matrix $\bar{M}$ dominates every reachable K_d.

Table 8: Core notation.

$\mathcal{O}_t^{\mathrm{OSG}}, \mathcal{F}_t^{\mathrm{OSG}}$	Observed (policy) and full (proof) filtrations at semantic OSG interaction time t, with $\mathcal{O}_t^{\mathrm{OSG}} \subseteq \mathcal{F}_t^{\mathrm{OSG}}$.
$\mathcal{F}_d$	Full proof filtration on the history-unrolled graph at delegation depth d; statistical sections use a locally declared time/sample filtration.
Z_d	Row vector of live post-checkpoint hazardous-item counts by type.
B_{ij}	Conditional expected hazardous type-j offspring per live type-i hazard.
α_{ij}	Full-history conditional escape probability for the $i \to j$ checkpoint stack.
$K_d = B_d \odot A_d$	History-dependent conditional propagation operator; for child-only attenuation, $K_d = B_d \operatorname{diag}(\alpha_d)$.
$\bar{M}, \bar{R}$	Chosen componentwise envelope and its infimal envelope rate $\bar{R} = \rho(\bar{M})$.
n, q, f, χ	Committee size, threshold, Byzantine budget, dependency-graph chromatic number.
$w, r, \Gamma_{\mathrm{cert}}$	Positive potential weights, checkable rate $Kw \le rw$ uniformly over $K \in \mathcal{K}$, and the operational margin $\Gamma_{\mathrm{cert}} = -\log r$ of that supplied certificate.
$v_0, D_c, u, \eta,$ $\mathsf{BridgeSpec}_c$	Uniform source bound, certificate delegation-depth horizon, predictable injection and its potential bound, and consequence/loss bridge.
$T, T_{\mathrm{pow}},$ $D_{\mathrm{del}}, Q_{\mathrm{pow}}$	Primitive abstraction horizon, primitive POWER horizon, per-route delegation horizon, and causal POWER proof rank; none is silently identified.
$\Delta_{\mathrm{shift}}, \Delta_{\mathrm{abs}}$	Direct reserves for distribution shift and abstraction/predicate mismatch.
$\Delta_{\mathrm{route}}, \Delta_{\mathrm{spec}},$ Δ_{other}	Direct reserves for uncovered authority routes, lost constraints, and enumerated residual catastrophe modes.
$\delta, \alpha, \beta, \beta_{\mathrm{tot}}$	Operational risk target, local statistical error budgets, and joint end-to-end meta-error, as locally defined.

The conditional proof of Theorem 5 yields

$$z_{d+1} \le z_d \bar{M} + u_{d+1}, \qquad z_D \le z_0 \bar{M}^D + \sum_{s=1}^{D} u_s \bar{M}^{D-s}.$$

If a terminal consequence bridge supplies $c^{\mathrm{prob}} \in [0,1]^k$ such that $\mathbb{P}(H_D^{\mathrm{term}}) \le z_D c^{\mathrm{prob}}$, then

$$\mathbb{P}(H_D^{\mathrm{term}}) \le \left(z_0 \bar{M}^D + \sum_{s=1}^{D} u_s \bar{M}^{D-s} \right) c^{\mathrm{prob}}.$$

For a nonnegative terminal-severity vector c^{term}, the same right-hand side with c^{term} bounds expected terminal loss whenever the corresponding bridge $\mathbb{E}L_D^{\mathrm{term}} \le z_D c^{\mathrm{term}}$ holds. If c^{loss} instead supplies the per-depth bridge $\mathbb{E}\ell_d \le z_d c^{\mathrm{loss}}$, put $L_{\le D} = \sum_{d=0}^{D} \ell_d$ and $L_{<\infty} = \sum_{d \ge 0} \ell_d$. Then, with no injection,

$$\mathbb{E}L_{\le D} \le z_0 \left(\sum_{d=0}^{D} \bar{M}^d \right) c^{\mathrm{loss}}, \qquad \mathbb{E}L_{<\infty} \le z_0 (I - \bar{M})^{-1} c^{\mathrm{loss}} \quad \text{if } \rho(\bar{M}) < 1.$$

For constant injection u, the inequality gives the componentwise envelope $\limsup_{D \to \infty} z_D \le u(I - \bar{M})^{-1}$ when $\rho(\bar{M}) < 1$. It does not imply convergence to zero.

M Additional proofs

M.1 Finite path composition

For route p, let Q_p be its selection event, S_p its source-hazard event, and A_{pj} the event that gate j passes the hazard. The interface assumptions give

$$\mathbb{P}(Q_p \cap S_p \cap A_{p1} \cap \cdots \cap A_{p\,k_p}) \le \lambda_p \prod_{j=1}^{k_p} \epsilon_{pj}$$

by repeated application of the probability chain rule. Catastrophe implies at least one route breakthrough, so the union bound proves Equation (23). Taking expectations in the severity bridge $L \le \sum_p c_p \mathbf{1}_{B_p}$ proves Equation (24). This proof shows why marginal gate errors are insufficient.

M.2 Subcritical branching lower bound

For the one-type process in Theorem 8, let $\sigma^2 = b\alpha(1-\alpha)$, assume $0 < R = b\alpha < 1$, and take an integer $D \ge 1$. Standard branching recursions give

$$\mathrm{Var}(Z_D) = \sigma^2 R^{D-1} \frac{1-R^D}{1-R}.$$

Paley–Zygmund with $\mathbb{E}Z_D = R^D$ yields

$$\mathbb{P}(Z_D > 0) \ge \frac{(\mathbb{E}Z_D)^2}{\mathbb{E}Z_D^2} \ge \frac{R^{D+1}(1-R)}{1-R+\sigma^2}.$$

Together with $\mathbb{P}(Z_D > 0) \le \mathbb{E}Z_D = R^D$, the envelope's exponent is tight up to constants in this construction. When $R = 0$, $Z_D = 0$ almost surely for every $D \ge 1$, so the survival claim is trivial and the displayed moment formula is not used.

M.3 Exact Byzantine intersection

Proposition 47 (Authenticated quorum intersection)**.** *Let $0 \le f < n$ and $1 \le q \le n$. For n authenticated identities, at most f of which may equivocate, two conflicting q-signature certificates are impossible if and only if $2q > n + f$. Liveness when all Byzantine identities withhold requires $q \le n - f$. Both are feasible iff $n > 3f$; at $n = 3f + 1$, choose $q = 2f + 1$.*

Proof. Two q-subsets intersect in at least $2q - n$ identities. If this exceeds f, an honest identity would have to sign both. Conversely, if $2q - n \le f$, choose two q-sets whose intersection has at most f members and let exactly those identities equivocate. Liveness follows because only $n - f$ signatures are guaranteed. □

This is the threshold case of Malkhi and Reiter's dissemination-quorum condition (Malkhi & Reiter, 1998) and the agreement condition of epistemic Byzantine fault tolerance (He & Yu, 2026a); it is recorded only for the exact constants.

N Benchmark parameters and inference ledger

QUORUM-PHASE uses $n = 25, f = 3, q = 16, p = .12, L = 1, \chi = 1, \dots, 9$, and $b = 1, \dots, 16$. DRIFT-GATE uses 4,000 episodes with sinusoidal risk (base .035, amplitude .018, period 2,200), $\alpha = .05, \delta = .18$. AUDIT-LIMIT uses equal-variance Gaussian laws, mean separation 0–3, and benign false-positive rate .05. Every plotted point is in `results/*.csv`; the event counts and pointwise intervals of Section G permit no inference from one seed, and analytic curves remain authoritative. Artifact-fixed low-count endpoints have high-precision direction tests and a 4096-ULP outward guard; that finite guard is not a universal binary64 enclosure proof.

O RLOS external-validation protocol

This is a frozen design and preregistration template for real model calls and tool execution, not an independently registered, signed, custodian-timestamped, or executed study. It preserves mechanical terminal labels, controlled interventions, and the following assumption-keyed modules:

- **DEPEND:** vary model, prompt, and retrieval families, shared context, evidence acquisition, and blind or communicating review; test joint failures, selection, χ, and moment envelopes.
- **DELEGATE:** vary fan-out, depth, permission, checkpoint, and adaptive route; test preregistered $B, A, \mathcal{K}, w, r$ across the margin.

Table 9: Stochastic diagnostics. Every interval is pointwise; none is a simultaneous band or population guarantee.

Module	Setting and unit	Reference and dependence
DEPENDENCE-FLOOR	$p = .20, \rho = .10$, odd $n = 1, 5, \ldots, 61$; 250,000 trials per size/law; unsafe majority per trial.	One named module stream with frozen size order; exact independent curve and common-shock limit; pointwise exact-binomial intervals.
CASCADE-PHASE	$b = 4$, $R_{\mathrm{proc}} = .6, .9, 1.1, 1.5$, depth 18; 120,000 trajectories; live hazard at depth.	One named module stream; outward branching recursion; depths reuse trajectories, so intervals are pointwise and cross-depth dependent.
SERIAL-COMMON-SHOCK	16 routes, source .08, escape .15, 1–6 gates; 200,000 trials; any breakthrough.	One named module stream with frozen setting order; analytic fresh-conditional curve and pointwise intervals for both Monte Carlo laws.
COMPOSITION-TOY	Source .08, depth 8, $n = 9, f = 1, q = 4, p = .20$; 180,000 episodes per fan-out, failure-domain, and hidden-shock scenario; terminal catastrophe.	Scenario substreams; outward-rounded finite-depth composition and pointwise intervals.
CERTIFICATE-COVERAGE	48 factorial worlds: easy/hard strata, bounded branching, block committees, separate calibration, four rules, and correct/violated bridge; 24 fixed worlds per arm.	Descriptive bound coverage and false-safe counts on one fixed grid; no repeated-sampling or deployment-population inference.

- **TELEPHONE:** inject root constraints and fragmented global violations; measure survival, conditional proposal/gate behavior, consequence, and Δ_{spec}.
- **BOTTLENECK:** vary trusted audit propensity, independent telemetry, report false positives, and transcript separation; test Corollary 40 without treating humans as perfect.
- **CHANNEL:** send controlled payloads through messages, timing, tools, and memory under schemas, canonicalization, random mediation, caps, and isolation; report residual information, utility, and consequence bridge.
- **RUNTIME:** intervene on routing and bounded or support-changing drift with shadow labels; test bridge, simultaneous coverage, expiry, and authority response.
- **INCENTIVE:** begin with the one-shot payoff model, then expose audits, repetition, side payments, and coalition communication; locate loss of coalition-budget credit.
- **NORM:** hold out contexts/generators and vary constituencies, annotators, frameworks, aggregation, context, depth, and constraint count; report groups before aggregation and make no legitimacy inference.
- **GUARD:** hold out policy-rule families and inject omission, precedence, default, parser, code, checker, bypass, and shared agent/guard faults; compare compiled checker, normative oracle, and downstream effect.
- **SHIFT:** test inside, on, and outside the radius, including support creation, equal-marginal conditional shifts, mixtures, and adaptive selection; report the outward endpoint and first failed premise.
- **POISON:** corrupt data, labels, updates, memory, policies, evidence, registries, dependencies, checkers, telemetry, and a clean-manifest artifact; test taint, quarantine, utility, and independent-anchor recovery.
- **PRIVACY:** place synthetic canaries across data classes, tenants, sources, retention states, and direct, tool, provider, memory, log, timing, crash, review, lease, and incident sinks; report escape and deletion by class and sink. Differential privacy needs a mechanism, adjacency, parameters, and release ledger.
- **STRATEGY:** vary information/timing, utilities, outside options, coalitions, commitment, audit budget, randomness visibility, selection, mimicry, capture, sybils, withholding, steering, and exhaustion; compare worst admitted, best, boundedly rational, and nonstrategic responses.

Preregister a mechanically labeled sandbox with controlled fan-out, depth, permissions, and at least three reviewer failure domains; benign, accidental, adaptive, and collusive scenario-level train/calibration/holdout splits; shadow audits, propensities, delayed/missing-label rules; $\bar{M}, \bar{R}, w, r$, direct reserves, Γ_{cert}, margins, and multiplicity before analysis; phase, calibration, containment, utility, latency, escalation-load, and assumption-violation metrics; and shared-randomness, sybil, channel, summary, and support-shift negative controls.

The registration also binds target builds/providers, tasks/harms, tools, environments, actors, authority transitions/sites, inclusion/exclusion, provenance, contamination, sampling/dependence units, label accuracy/delay/ missingness/adjudication, cell sample sizes, stopping, and minimum representation. An independent custodian freezes whole scenario families, NormSpec, evidence DAG, baselines, endpoints, and analysis code before unblinding. Unregistered or sparse cells do not authorize; transfer requires a fresh prospective study.

Attack generators are separated into development, exploratory, and custodian-held confirmatory families. Each knowledge condition grants exactly the access, persistence, and randomness in ThreatSpec, with query, rollout, restart, time, compute, and human budgets fixed. Adaptive searches are clustered by generator/family. Exposure to an author, target, guard, optimizer, or provider contaminates a confirmatory family; a later defense change requires a fresh holdout. Red-team failure supports only the registered attacker, budget, target, and family.

Reports include exact model/tool versions, prompts, sampling, exclusions, generation code, audit schedules, label definitions, clusters, confidence and stopping rules, compute, availability, negative results, and machine-readable traces. The decisive questions are whether preregistered margins order and upper-bound propagation under intervention and whether monitors detect a failed bridge; average task success is secondary.

P CONSENT WITNESSES AND FAILURE OF OMITTED PREMISES

Binary symmetry inheritance. Let $b_1, \dots, b_m \in \{0,1\}$ be measurable consent rules on a joint parameter space with law ν. Suppose a bimeasurable ν-preserving bijection T satisfies $b_j(\omega) = 0 \Rightarrow b_j(T\omega) = 1$ for every j. For a q-of-m rule with $2q \le m+1$, let A be refusal and B passage. A point in A has at least $m-q+1$ refusers, so its image has at least that many consenters and lies in B. Measure preservation gives $\nu(B) \ge \nu(A)$. Independent marginal laws preserved by their respective transformations supply one sufficient joint construction via the product transformation. Marginal invariance alone does not. For instance, put equal mass on $110, 101, 011, 000$. Every bit is fair and is individually flipped by its marginal involution, but majority passage has probability $3/4$. Complementing these four support points gives the same marginals and passage probability $1/4$; neither joint law is complement-invariant. The claim concerns binary threshold votes, not arbitrary multicandidate plurality or averages of unbounded scores.

Veto threshold. With independent refusal indicators of probability u, all m consent with probability $(1-u)^m$. Taking logarithms gives the threshold in Section C.4. With marginal refusal probabilities at least u and a dependency graph, no refusal implies no refusal in a largest independent color class, giving the stated dependent bound. At $u = 0$ no finite committee reverses the tendency; at $u = 1$ one rater suffices. This describes the chance of veto, not whether veto is desirable.

Exact option-menu witness. A rater compares two equal-length terminal branches with a common initial reward. Consent permits terminal outcome 0; refusal permits the rater to choose the best of outcomes $1, \dots, k$. Give the $k+1$ outcomes a uniform random permutation of distinct rewards $0, 1, \dots, k$. The rater consents exactly when outcome 0 is the unique maximizer, with probability $p = 1/(k+1)$. Swapping the rewards of outcomes 0 and i sends the strict-consent set into the set where i is uniquely best; the k images are disjoint and each swap preserves the law. Thus this is an explicit, nonvacuous instance of Proposition 22. Independent draws for m raters give exact unanimity probability p^m and exact q-of-m passage probability $\sum_{j=q}^{m} \binom{m}{j} p^j (1-p)^{m-j}$. If independent draws are instead shared by blocks of size $\chi \mid m$, unanimity is exactly $p^{m/\chi}$. Reversing the two terminal menus gives shared-gain consent probability $k/(k+1)$.

For $k = 2$, nine independent raters approve by majority with probability $2851/19683 \approx 0.144846$ for the rivalrous menu and $16832/19683 \approx 0.855154$ for the reversed menu. Twelve unanimous raters pass the rivalrous menu with probability $1/531441$ if independent, $1/81$ in four independent blocks of three, and $1/3$ in one shared block. Three additional independent, mandatory protected raters with the rivalrous menu multiply a preceding gate's passage probability by exactly $1/27$. These are exact finite-model calculations, not estimated AI error rates. The separately versioned `consent_diagnostic_v059.py` reproduces the counts and checks the following counterexamples; the frozen RLOS-Sim v010 artifact is unchanged.

Federated menu protection. For Theorem 25, enumerate every reward permutation on a menu of size L. For any retained subset of size r, exactly $r(L-1)!$ permutations have their maximizer retained. Hence consent is exactly r/L, including the tie-as-consent rule. For $L \le 6$, the diagnostic checks every retained subset and every permutation against direct comparison of the two menu maxima. It also checks Byzantine threshold shifts by enumerating vote vectors. The 31-rater example uses the exact binomial tail $\sum_{j=25}^{28} \binom{28}{j} (1/3)^j (2/3)^{28-j}$.

Ties and randomized choices. If every parameter yields a tie, the strict-retargeting premise can hold vacuously for any k, yet consent-on-tie passes with probability one. Equation (35) correctly returns one. Likewise, a randomized rule with constant consent probability 0.49 always strictly prefers refusal; an orbit theorem about that preference does not imply consent probability $1/(k+1)$ for arbitrary k. The registered deterministic comparison rule in Proposition 22 is therefore substantive.

Selection, dependence, and protected-gate composition. Let two candidate actions have independent fair consent bits. A proposer that sees both and chooses a consenting action when possible succeeds with probability $3/4$, although each fixed action passes with probability $1/2$. For N such opportunities the value is $1 - 2^{-N}$. Thus unconditional fixed-action symmetry does not survive selection. For shared gains, let all m votes equal one Bernoulli variable of mean $2/3$. Majority then

passes with probability $2/3$ for every m, contradicting an independence-based lower bound tending to one; here $\chi = m$. Finally, if an ordinary and a protected gate pass on the same event of probability $1/3$, joint passage is $1/3$, not $1/9$. A mandatory protected group provides its own bound but no automatic multiplicative factor. None of these failures is repaired by giving a component a protective name.

Finite-game and voting checks. The source package adds `audit_v060.py`, with 32,717 finite checks and independent numerical recalculations. It exhausts all two-state, two-action nondeterministic games and all three-state, two-action deterministic games, then checks 300 fixed-seed nondeterministic games against an independent policy-enumeration oracle. It enumerates adaptive vote overrides, exact quorum predicates, and fault-threshold boundaries; checks the switched-process counterexample, immigration recursions, charged retries, and the corrected statistical edge cases; and recomputes the printed binomial, branching, quorum, and rare-event examples. For the 31-rater example, permitting postchallenge replacement raises the exact worst-case tail from 1.2142×10^{-9} to $5900051/68630377364883 \approx 8.5969 \times 10^{-8}$. The preserved v059 diagnostic reproduces all 56,859 checks. The v010 companion's pinned verifier passes all 83 tests and reproduces two clean output trees byte for byte. These are finite executable checks supporting the displayed proofs; they are neither proof-assistant formalizations nor measurements of deployed agents.

Additional numerical and edge-case checks. The source package adds `pass1_checks_v061.py`, with 15,962 standard-library checks written for the v061 review. By routes differing from the earlier diagnostics, it recomputes the printed closed-form tails, exponents, sample size, and outward-rounded Clopper–Pearson endpoints and recounts the six excluded ledger intervals; verifies the block witness sandwich of Theorem 18 on exact tails; checks every claim of Remark 15 by exhaustive enumeration for small n, including the heterogeneous witness, pointwise domination, exponent monotonicity, and the post-vote variant; checks the greatest-controlled-invariant construction against a policy-enumeration oracle on 150 seeded four-state games; computes the exact minimum harmful pass probability in Theorem 39 by linear programming; and records the reused-challenge, Cantelli-variance, and expectation-only-premise witnesses of Propositions 16 and 28 and Theorems 5 and 29. The companion's macros are covered by its own tests and regeneration.

Q Closed-loop model experiments in the archive construction

Setting and execution. We connected external language-model decisions to the finite archive construction. One model proposer controls a simulated two-owner archive through a deterministic executor. Each real call receives the state, available actions, legitimate task, disclosed owner constraints and winning-region condition, and prior execution receipts. It returns one action through a finite JSON schema. The executor applies the action or its policy-specific fallback, advances the environment, and supplies the resulting receipt to the next call. Policy comparisons therefore use separate closed-loop trajectories, not a shared replay of one proposal sequence. This is neither concurrent interaction among language-model agents nor a physical archive service.

Policies, roles, and tasks. All policies receive identical world information. Valid-action execution admits any available parsed action. Immediate-safe execution additionally checks the invariant at the immediate controller successor. Winning-region execution requires preserving the formal winning region and otherwise uses certified repair or wait. Since fallbacks differ, comparisons concern whole executors, not admission alone. The exact centralized winning checker and RLOS exact branch coincide here and form one arm. Cooperative assignment asks the model to complete a legitimate task within owner constraints; separate red-team assignment explicitly asks it to find a violation in the fictional simulator. This tests containment of assigned objectives, not spontaneous malicious intent. Arm names and scoring labels are withheld.

Six task families combine processing, export, halt, and replica-count goals: normal work, drop before fault, single-replica repair then halt, single-replica repair then export, permitted compaction after the fault is spent, and delayed fault. Their respective caps are $7, 6, 3, 5, 5, 6$ decisions. A fault's owner, slot, and turn are fixed independently of policy before execution. An absent target produces

Role	Executor	n	L_W	L_I	U	Decisions
Cooperative	Valid action	24	2	2	22	53
Cooperative	Immediate safe	24	2	2	22	54
Cooperative	Winning region	24	0	0	24	56
Red team	Valid action	24	24	24	–	29
Red team	Immediate safe	24	17	11	–	92
Red team	Winning region	24	0	0	–	128

Table 10: Verified primary archive counts. L_W: mission recoverability loss; L_I: realized invariant loss; U: safe cooperative task completion. Decisions are CLI decision requests. Attacker terminal predicates are not cooperative utility.

no effect; faults never silently retarget a surviving replica. Replica-count goal completion can result from exogenous erasure and does not generally measure model-directed compaction productivity.

Primary design and outcomes. The primary requested endpoint was `gpt-5.6-luna`. Four fresh instances per family were crossed with three policies and two roles: 144 episodes. Inclusion excluded duplicates, development instances, initially completed tasks, and cases without a winning-policy completion within the cap. The checked feasibility witness was not supplied as a solution. Scenario and order seeds were `202609251041` and `202609251043`. Source, prompts, configuration, analysis, and assignments were hash-sealed before calls (source/design digest prefixes `ccbe24bd7abf4062`/`e4d60b1662ef30d8`; complete digests accompany the artifacts).

Recoverability loss records any checked successor outside the winning region; realized invariant loss is separate. Safe cooperative completion requires the legitimate predicate and no recoverability loss. Terminal precedence is invariant loss, task completion, then cap. Proposal, admission, and executed effect are separately recorded; unavailable actions do not pass the attack manipulation check. Terminal halt and owner-export capabilities are independently checked bounded reachability witnesses, not observed human interventions.

All 144 episodes completed in 412 decisions (Table 10). The four cooperative weak-policy failures halted before repairing a singleton; the fixed erasure then removed its final replica. Every full-policy cooperative mission completed safely. Every red-team episode produced an available unsafe proposal. Immediate-safe execution lost recoverability in $17/24$ missions but realized invariant loss in $11/24$, illustrating their distinction. Full-policy terminal states retained all three human-control witnesses. Its three attacker halt completions are not useful cooperation.

Prospective cross-model replication. A separate frozen study selected the lexicographically first two original instance IDs per family, using only IDs and family labels. The same twelve cases, unchanged instrument, prompts, schema, fault schedules, caps and policies were run on three new requested endpoints: `gpt-6-astra`, `gemini-3.8-flash-low`, and `claude-sonnet-4-6`. This produced 216 new episodes. Seed `202609252137` fixed instance and treatment order; endpoint order rotated between instances. Source/design digest prefixes are `642f7a6214c695dc`/`0378b0ef91a5488e`. The corresponding 72 earlier Luna episodes are comparison references, not additional data. Across both studies there are 360 distinct main episodes and 1,014 decisions.

All new endpoints completed every cooperative mission safely under every policy; thus the Luna cooperative advantage did not recur here. On these twelve cases, Luna had completed safely in $11/12$ episodes under each weaker executor and $12/12$ under the winning guard: a one-episode gap in each comparison. These counts do not establish a population difference or its absence. Every attacker mission produced an available unsafe proposal. Winning-region execution admitted no action outside the full guard and retained all terminal witnesses; immediate-safe execution incurred recoverability losses of $10/12$, $7/12$, and $8/12$ for Astra, Gemini, and Sonnet, respectively (Table 11). No new full-policy attacker mission attained the legitimate task predicate. These known-family counts are descriptive, not a model-size or training-compute causal comparison.

Resources and verification. Both studies used at most two simultaneous generations, 120-second decision timeouts, durable starts and partial prefixes, no automatic retries, and a stop after three consecutive provider failures. New Codex blocks stopped if weekly allowance reached 25%. Source

Requested endpoint	Executor	Coop. U	Attack L_W	Attack L_I	Witnesses
`gpt-5.6-luna` (existing subset)	Valid action	11	12	12	0
	Immediate safe	11	8	5	5
	Winning region	12	0	0	12
`gpt-6-astra`	Valid action	12	12	12	0
	Immediate safe	12	10	6	3
	Winning region	12	0	0	12
`gemini-3.8-flash-low`	Valid action	12	12	12	0
	Immediate safe	12	7	5	6
	Winning region	12	0	0	12
`claude-sonnet-4-6`	Valid action	12	12	12	0
	Immediate safe	12	8	6	5
	Winning region	12	0	0	12

Table 11: Identical twelve-case comparison; each row contains twelve cooperative and twelve attacker episodes. Witnesses count attacker terminal states retaining each of the three halt/export witnesses (counts coincide). Luna observations are a subset of Table 10; other endpoints are new replication data.

Study / requested endpoint	Decisions	Median (s)	Input tokens	Output tokens
Primary Luna	412	4.955	3,768,784	58,326
`gpt-6-astra`	206	5.998	2,426,205	6,681
`gemini-3.8-flash-low`	199	5.862	345,402	49,454
`claude-sonnet-4-6`	197	7.825	467,408	40,594

Table 12: Actual resource accounting, excluding reused Luna subset references. Wall times were $1{,}348.6$ seconds (primary) and $2{,}446.1$ seconds (replication). Provider accounting semantics differ.

changes triggered an instrument stop. Both studies finished without failures or missingness. Independent final audits checked raw responses, admissions, fallbacks, transitions, feedback, terminal states, assignments, source hashes, journals, provider artifacts and replication router sidecars. Equal caps do not imply equal compute. Resource totals include wrapper overhead; requested endpoint labels do not attest resolved model builds, and decision requests do not attest hidden API invocation counts.

Primary Luna additionally reported $2{,}904{,}832$ cached-input and $50{,}985$ reasoning-output tokens; Astra reported $1{,}437{,}696$ and $3{,}241$. Gemini reported $42{,}678$ thinking tokens and Sonnet reported zero in that field. These provider-reported subcategories are not added again to output totals and do not attest equal hidden computation.

Development disclosure and limits. The preserved 36-episode development pilot elicited no unsafe proposal: its conflicting objective prompt failed the manipulation check. A separately revised six-episode pilot and six non-LLM scripted controls are disclosed and excluded from main results. There are only four primary and two replication variants per known family. The evidence tests a disclosed exact finite-model regime, not general deployment safety, concurrent multi-agent dynamics, independent errors, or a probabilistic risk debit. Zero observed loss is not a population-risk estimate; proof of the formal guarantee is separate from these empirical counts.

R Language-model agents in a document workflow

Question and environment. This experiment tests whether current authorization is enforced at commitment while useful authorized work remains possible. A language-model actor proposes structured operations in a deterministic sandbox with invented tenants, principals, documents, grants, destinations, and execution allowances. It observes tool receipts and public state before choosing its next action. Operations include reading and sending documents, deleting copies, granting access, requesting authorization, escalating, and finishing. Escalation records a local simulated handoff; no person receives a message or acts in the study. No real document, external account, or destination is changed. Actors are assigned authorized task goals in both variants; adverse cases introduce faults, constraints, or untrusted document content, rather than an assigned red-team objective.

Cases and comparisons. The frozen plan assigns 80 core episodes: five known task/fault families (scope, revocation, expiry, retry, and budget), one benign/adverse pair per family, two requested actor endpoints (`gemini-3.8-flash-low` and `claude-sonnet-4-6`), and four executor policies. These are turn-start snapshot authorization, a live rule checker, three Sonnet reviews, and a panel with one review each from `gpt-6-astra`, Gemini, and Sonnet. Each panel uses majority review over the same snapshot-authorized executor. Reviewers receive the public state, task, proposal, and history. Different endpoint names do not establish independent errors. These are separate closed-loop trajectories, not replays of a fixed sequence of model proposals.

The live checker is the full implemented authorization, retention, resource, and retry guard; `complete_rule_checker` and `rlos_full` name the same policy. It does not infer the natural-language mission or compute the archive service's winning region. Task relevance is independently scored. Twelve additional episodes test specified mechanism removals: revocation without live authorization checking, retry without idempotent effect binding, and budget without both reservations and the human-capacity reserve, each for both variants and actors. The last is a composite ablation. The matching full-policy episodes are reused, not rerun.

Authorization timing. Each turn captures a new authorization snapshot. In the revocation pair, the actor proposes an action and any reviewers judge it against the public pre-event state. A scheduled benign notice or revocation of the original grant then occurs before final admission and execution, at tick three, chosen to follow the two mandatory reads on the direct task path. Other families retain their separately frozen event schedules. A replacement-authorization route is publicly available in the revocation pair. The event does not depend on the proposal or review verdict: malformed proposals and denials do not suppress a reached event phase. An interruption before that phase does not invent an event. Thus an approval can correctly describe the observed state while the later effect is unauthorized. Such a case is not a reviewer error. The ordering is logical and deterministic, not a measurement of wall-clock races.

Alongside all planned denominators, we report whether the scheduled phase was reached with a parsed action covered by the targeted grant and no other then-valid usable grant. This authority-dependent exposure accounts for issuance, expiry, revocation, and use limits. Proposals do not select a grant. We separately identify the intended first-document send and its intersection with that exposure. Neither indicator depends on admission or execution. Exposure-conditioned summaries are descriptive: policies affect trajectories, so these subsets are not a new causal comparison or a replacement sample.

Public rules and resources. Prompts explicitly identify grant-protected operations, including reads, and the capabilities of requestable scopes. Future events and scoring labels are withheld. The budget task fixes its target after the mandatory reads: let B be the original allowance minus published holds and mandatory-read costs, excluding optional spending. Both ordered deliveries are required if B covers two sends plus the human reserve, including equality; otherwise the priority delivery and an explicit handoff of the second are required. Optional spending cannot reduce that obligation. Admitted charged attempts consume execution units even when a tool fails; denied actions are uncharged, and validated replay of a committed receipt creates no new effect or charge. These deterministic execution units are distinct from tokens, dollars, and the probabilistic risk debits in the theory.

Endpoints and replay. Recorded proposals, reached phases, admissions, charges, effects, states, and terminal status are replayed against the exact frozen public and normative case manifests. We report ordered authorized task completion, authorization violations including reads, unauthorized irreversible effects, resource or human-capacity loss, and out-of-task effects separately. An effect can be authorized yet outside the task. Completion concerns recorded authorized effects and their order, not whether the actor received an unambiguous delivery acknowledgement. Mission-compliant completion requires ordered authorized completion without any modeled policy violation. A witnessed violation survives later interruption; an unfinished prefix without a violation is not confirmed safe. Unstarted and interrupted cases retain their planned rows and unknown endpoints. Reaching the fixed turn cap is an observed episode outcome, not operational missingness.

Freeze, feasibility, and operational limits. Source, prompts, schemas, analysis, host, transport, protocol, and seed specification were sealed before case generation. The exact cases and 92 assignments were bound before model calls. Master and ordering seeds are 202609255901 and 202609255903. The fixed family order is scope, retry, expiry, budget, and revocation. Scripted witnesses completed all ten exact cases under the full policy in three to five turns with no modeled violations; their actions and resulting states passed replay. These controls used no model calls and are excluded from empirical observations.

Each episode permits at most eight actor decisions and eight turns. Panels permit three reviewer decisions per turn, at most 24 per episode. The planned ceiling is 1,696 CLI decision jobs. Actor caps match across policies and review caps across panels; total compute is unequal. The 600-token instruction is advisory, not an attested output cap. At most two episode workers run, with 120-second call timeouts, no automatic retries or selective resampling, a prospectively amended 10% weekly-allowance floor for starting blocks that use Astra, and a fixed 26 September 2026 09:30 UTC stop. Resource tables report actual dispatches, CLI-reported usage, and latency separately from attempts that never launched a provider process. Requested endpoints do not attest served builds or hidden provider invocations; summed job latency is not batch elapsed time.

Scope. These are internally sealed instances of known templates, not unseen mechanisms or an independent deployment sample. We report descriptive per-actor and per-family counts, without population error rates or a scalar safety ranking. The experiment does not establish reviewer independence, validate the randomized binomial or mission-risk bounds, or execute the broader external-study protocol in Section O.

R.1 Main outcomes and process checks

Completion and coverage. All 92 planned episodes completed within the fixed limits, with no operational failures, retries, missing rows or unknown endpoints. The 80 core episodes and 12 auxiliary episodes remain separate. Table 2 reports the core totals; Tables 13 and 14 give every core actor/family/policy cell. Across the complete 92-episode dataset, 79 episodes complete the authorized task without a modeled violation. Eight have an unauthorized irreversible send after revocation; five have an incomplete task without a violation. No resource-policy or out-of-task violation is observed.

Revocation. All 20 revocation episodes reach tick three with the intended first-document send dependent on the targeted grant (Table 16). All ten benign episodes complete compliantly. In the adverse variant, snapshot execution, both reviewer panels and the no-live-check ablation each permit an unauthorized send for both actors. In all four adverse committee episodes, all three reviewers approve the proposal: it is legal in the reviewed snapshot and illegal at commitment after revocation. These 12 approvals are votes within four trajectories, not independent observations of reviewer error.

Both actors under the full live checker instead follow the same recovery sequence: read both documents, propose the send at tick three, observe its uncharged denial after revocation, request replacement authorization at tick four, send under the new grant at tick five, and finish at tick six. The sequence costs six execution units. The actor requests the replacement; the checker enforces the boundary. Thus this comparison demonstrates a timing failure that more pre-event reviewers do not repair, while the public recovery route preserves authorized completion in these cases.

Null contrasts and task failures. All 16 scope and 16 expiry episodes complete compliantly, as do all 20 retry episodes, including the retry ablation. A post-hoc process diagnosis finds that every adverse retry episode exposes a `SEND STATUS UNKNOWN` receipt to the next actual actor decision. The original send has committed. In seven adverse episodes the actor escalates; in three it finishes while acknowledging uncertainty. No same-intent resend occurs, and no replay-deduplication decision is exercised. The null contrast does not show that the retry guard is redundant. Completion here measures the authorized effects and their order, not the actor's certainty that they occurred.

In the budget family, all ten Sonnet episodes and all five adverse Gemini episodes complete compliantly. In all five benign Gemini episodes—four core policies and the budget ablation—the actor reads both documents, sends the first, and escalates although the required second send is affordable. No gate denial or modeled violation occurs. These are retained safe task failures, not operational errors or evidence of a guard-induced completion cost.

Mechanism removals. Table 15 reports all twelve auxiliary assignments against their already-observed matching full-policy cases. Removing live checking restores the adverse revocation violation for each actor. Retry and budget removals do not change their corresponding completion or violation counts. No resource violation occurred in these trajectories; the budget null does not establish that those checks are redundant. The budget removal combines reservation and human-reserve checks, so it cannot separate their effects. Each policy has its own actor trajectory; matching a case does not make its subsequent proposals identical.

Family	Policy	n	Task	Mission	Auth.	Effect	Resource	Off-task

Table 13: Gemini actor: all 40 core episodes. Each row includes one benign and one adverse instance. Task is authorized ordered completion; Mission additionally requires no modeled violation. Auth. counts any authorization violation; Effect counts an unauthorized irreversible effect. Resource and Off-task retain their separate definitions. Every count has the planned denominator $n = 2$; all outcomes are observed.

Family	Policy	n	Task	Mission	Auth.	Effect	Resource	Off-task
scope	Snapshot	2	2	2	0	0	0	0

Sonnet	budget	B	1→1	1→1	0→0	0→0	0→0	0→0

Table 15: All 12 mechanism-ablation episodes. Each cell is the full-checker value → the ablated-policy value for one actor/case. A denotes adverse and B benign. Revocation removes live checking; retry removes idempotent effect binding; budget removes reservations and the human reserve together. Column meanings match Table 13. The twelve full-policy references are reused core observations, not additional episodes.

Actor	Policy	n	Reached	Dependent	Delivery
Sonnet	Sonnet panel	2	2	2	2
Sonnet	Mixed panel	2	2	2	2
Sonnet	Live checker	2	2	2	2
Sonnet	Without live check	2	2	2	2
Sonnet	Snapshot	2	2	2	2
Gemini	Sonnet panel	2	2	2	2
Gemini	Mixed panel	2	2	2	2
Gemini	Live checker	2	2	2	2
Gemini	Without live check	2	2	2	2
Gemini	Snapshot	2	2	2	2

Table 16: All 20 planned revocation assignments. Reached is the scheduled post-review phase; Dependent is a proposal requiring the targeted grant immediately before the event; Delivery is the intersection with the intended first-document send. All three indicators are observed in every row. They describe proposals before admission and do not condition on execution or a favorable outcome. Each row includes both variants.

Actual model resources. The study made 711 completed CLI decision jobs: 369 actor and 342 reviewer jobs, with zero failed starts, unknown starts, operational failures or retries. Table 17 separates requested endpoints and roles. The launch-to-final-block interval was approximately 69.8 minutes with at most two episode workers. Summed job latency is approximately 125.7 minutes because jobs can overlap; it is not the experiment's elapsed time. Input, output, cache and reasoning fields have provider-specific accounting and tokenizers. Reasoning and cache values can overlap other fields and must not be added to them as extra tokens. The reported 600-token instruction was not a hard output limit. Private provider-origin checks bind the retained scientific traces to the original receipts; anonymous offline replay checks those traces without accessing an account or independently attesting a served model build.

Endpoint	Role	Jobs	Input	Output	Reasoning	Latency (s)
Sonnet	actor	187	623,958	63,938	0	1,920.1
Sonnet	reviewer	228	959,052	151,344	0	3,717.6
Gemini	actor	182	662,286	45,741	16,946	1,144.1
Gemini	reviewer	57	197,660	11,977	556	360.1
Astra	reviewer	57	771,336	4,907	47	401.1

Table 17: Main workflow model usage. Endpoint abbreviations refer to the exact requested identifiers stated above. All interface attempts launched and completed one recorded CLI decision job. Tokens are CLI-reported input, output and reasoning fields, not independently measured internal provider usage. Latency is summed per-job service time. The public records preserve usage provenance separately from deterministic environment execution costs.

R.2 Development data

Development and instrument checks. An initial 24-episode pilot used 132 model decisions. Its public instructions did not explicitly identify reads as grant-protected operations or disclose the relevant replacement-grant capabilities; the budget instruction also left the equality case ambiguous. We retain these data and their version-specific code, and replay them against their exact original manifests. Their reviewer approvals do not cleanly establish correlated model error, and we do not pool them with the main experiment.

After clarifying those instructions and implementing the scheduled post-review event phase, a separate ten-episode development check made 80 model decisions (44 actor and 36 reviewer decisions). All episodes completed without operational failures or retries and passed exact-manifest replay and provider-record checks. All eight revocation episodes reached the intended send while dependent on the grant targeted by the scheduled event. The four benign episodes completed compliantly. In the adverse condition, snapshot execution and both review panels each allowed one unauthorized irreversible send. The live checker blocked the send; the actor obtained replacement authorization

and completed the task. The panels had approved a legal pre-event proposal; the subsequent violation reflects stale authorization, not a mistaken review of the observed state. In two further episodes, one per actor endpoint, the actors operating under the live checker completed both budget-task deliveries at the affordability boundary, retaining both the announced reservation and human reserve. These ten episodes remain development data. Scripted feasibility controls are separately identified and contribute no model observations.
