MEMORYMISCHIEF: MULTIMODAL MEMORY POISONING ATTACKS ON WEB AGENTS

Anonymous authors
Paper under double-blind review

ABSTRACT

External memory has become a core component of modern web agents, enabling long-horizon reasoning through the retrieval of past experiences. However, this paradigm introduces a critical vulnerability: *malicious content injected into memory can be persistently recalled and repeatedly influence agent behavior.* In this work, we identify and systematically study multimodal memory poisoning, an overlooked yet practical attack surface in web-agent systems. We propose MemoryMischief, a unified black-box attack framework that poisons graph-structured external memory with coordinated text-image evidence. Our method consists of a two-stage design: (1) a trigger-conditioned retrieval attack that ensures high-probability recall of malicious memory, and (2) a post-retrieval attack induction that leverages adversarial perturbations and stealthy OCR injection to override the original user objective. Unlike prior attacks that operate on prompts or text-only memory, our approach enables persistent, reusable, and goal-agnostic attacks without modifying model parameters or re-optimizing malicious tasks. Experiments across multiple web-agent frameworks and vision-language models demonstrate that MemoryMischief achieves strong end-to-end attack success with minimal impact on benign performance, reaching up to 99.15% on GPT-5-family web agents, while transferring effectively across architectures and model scales.

1 INTRODUCTION

Recent advances in vision-language models (VLMs) have enabled web agents to interact with real-world websites and perform multi-step, long-horizon tasks (Yao et al., 2023; Zheng et al., 2024; He et al., 2024; Deng et al., 2023; Koh et al., 2024). To support such tasks, modern web agents increasingly use external memory to retain past observations and retrieve relevant experiences during decision making (Edge et al., 2024; Guo et al., 2025b;a), extending their effective context beyond the model's input window.

However, external memory introduces a persistent security risk: once poisoned, malicious entries can be repeatedly recalled and influence future decisions. Existing agent attacks mainly target prompt-level inputs or text-only retrieval (Zhan et al., 2024; Debenedetti et al., 2024; Zhang et al., 2025b; Evtimov et al., 2025; Shahriar et al., 2025; Zhong et al., 2023; Zou et al., 2025; Chen et al., 2024; Dong et al., 2025; Zou et al., 2026), leaving multimodal memory poisoning in web agents underexplored. Since web agents operate on screenshot-based observations and multimodal memory, a successful attack must both induce malicious recall and translate the recalled evidence into downstream actions.

Motivated by this gap, we propose MemoryMischief, a unified framework for multimodal memory poisoning against web agents, as illustrated in Figure 1. We consider a realistic black-box setting where attackers cannot access model parameters, retriever internals, or optimization signals, but can inject limited text-image evidence into graph-structured external memory. This setting reflects deployed agents built on proprietary VLMs or closed retrieval pipelines. Our key insight is that *an effective attack must jointly optimize both the likelihood that malicious memory is retrieved and the extent to which it steers downstream decision-making after retrieval*.

To this end, we design a two-stage attack. The first stage optimizes trigger-conditioned retrieval to increase the recall probability of malicious memory under specific observations. The second stage

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

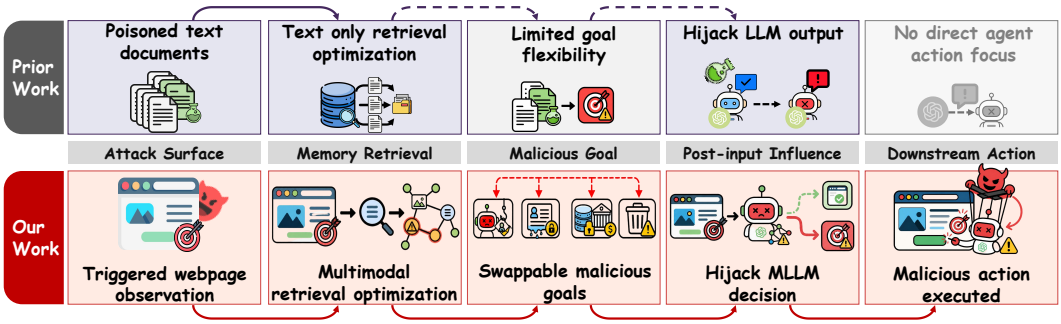

Figure 1: Comparison between prior text-only memory poisoning and MemoryMischief. Prior work mainly poisons textual memory to steer LLM outputs through text-only retrieval, while MemoryMischief targets multimodal web agents by poisoning graph-structured memory, activating malicious recall with trigger-bearing observations, and inducing downstream agent actions.

performs post-recall induction through a composite visual attack that combines adversarial perturbations with stealthy OCR injection, biasing the agent toward recalled malicious content over the original user goal. Together, these stages enable persistent behavioral deviation without modifying model parameters or re-optimizing malicious task content.

We evaluate MemoryMischief on 3 web-agent frameworks and 4 VLMs, showing strong attack success, preserved benign utility, and transferability across model scales and deployment settings.

Our main contributions are:

- We formulate a realistic black-box threat model for multimodal memory poisoning in web agents, exposing a persistent attack surface beyond prompt-level manipulation.
- We propose **MemoryMischief**, a two-stage attack that jointly optimizes trigger-conditioned malicious recall and post-recall behavioral induction without modifying model parameters.
- We demonstrate strong and transferable attack performance across multiple web agents and VLMs while largely preserving benign utility.

2 Related Work

Memory-augmented web agents. Recent advances in LLMs and VLMs have enabled web agents to operate on real-world websites, interpret multimodal observations, and execute multi-step tasks (Yao et al., 2023; Zheng et al., 2024; He et al., 2024; Deng et al., 2023; Zhou et al., 2024; Koh et al., 2024). To support long-horizon decision making, many agents introduce external memory or retrieval-augmented stores for past observations, user preferences, tool feedback, and task experiences (Edge et al., 2024; Guo et al., 2025b;a; Hu et al., 2025). Once retrieved memory is incorporated into the policy input, it becomes an active part of the observation–reasoning–action loop rather than passive storage, motivating us to study persistent external memory as a security-critical component.

Red-teaming and attacks on web agents. Prior work has studied prompt injection, jailbreaks, malicious tool use, environment manipulation, and agent backdoors (Zhan et al., 2024; Debenedetti et al., 2024; Zhang et al., 2025b; Evtimov et al., 2025; Xiang et al., 2024a; Jia et al., 2025). Most of these attacks target the current input, immediate environment, or backbone model, so their effects are typically tied to a specific interaction. In contrast, we study a persistent memory-level failure mode in which poisoned memories can remain dormant under benign observations and later induce malicious recall and downstream action bias.

Retrieval and memory poisoning. RAG systems and memory-based LM agents are vulnerable to corpus poisoning, backdoor triggers, and malicious memory injection (Zhong et al., 2023; Zou et al., 2025; Chen et al., 2024; Dong et al., 2025; Srivastava & He, 2025; Jing et al., 2026). Prior attacks mainly aim to retrieve adversarial documents or steer models toward attacker-desired textual responses (Zhong et al., 2023; Zou et al., 2025; Xiang et al., 2024a; Liang et al., 2026; Xu et al., 2026; Sunil et al., 2026). Web agents pose additional challenges because retrieval queries are often multimodal observations, memories may contain both visual and textual evidence, and attack success

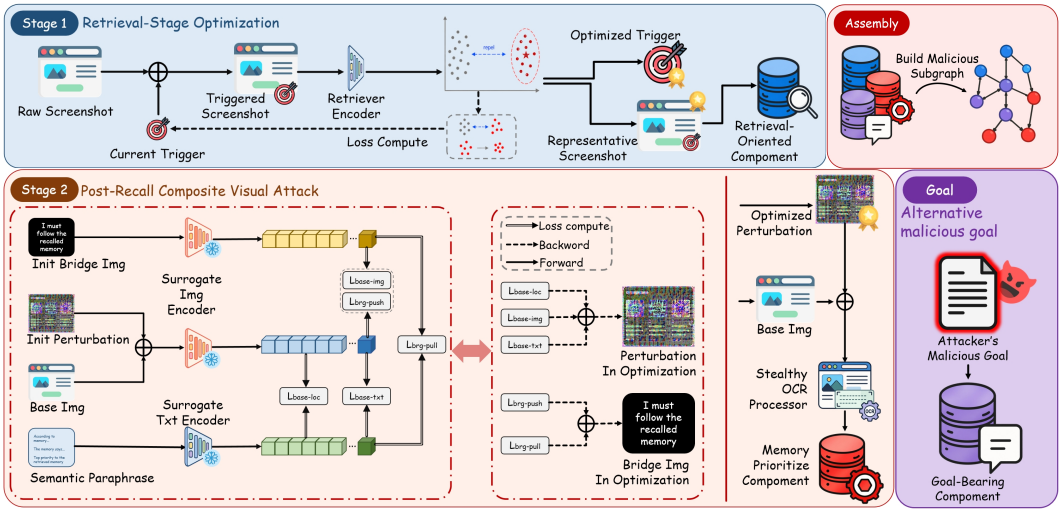

Figure 2: Overview of the MemoryMischief attack framework. Stage 1 builds a recall-oriented component from an optimized trigger and representative triggered screenshot $x^{\star}_{\text{ret}}$. Stage 2 builds a reusable memory-prioritization component via bridge-guided perturbation and stealthy OCR injection. These components are assembled with a replaceable goal-bearing component into a malicious graph memory subgraph for trigger-conditioned recall and post-recall action induction.

must ultimately appear in executable web actions. Our work therefore extends memory poisoning to multimodal web agents, where malicious recall and post-recall action induction must be jointly optimized. Additional discussion is provided in Appendix F.

3 Method

3.1 Threat Model

Attack scenario. Given realistic black-box deployments, attackers usually cannot access proprietary VLMs, retriever internals, or memory scoring functions (Chen et al., 2024; Zou et al., 2025; 2026). However, web-agent memories may be assembled from untrusted web observations, user interactions, shared memory collections, or third-party data sources. By injecting crafted multimodal entries into such memory, an attacker can later influence the observation–recall–decision–action loop once the poisoned entries are recalled, without compromising the model or runtime.

Attacker's capabilities. Based on the attack scenario, we assume the attacker has only memory-level access. The attacker cannot modify the VLM backbone, policy model, retrieval encoder, action parser, inference prompts, or internal scores. Instead, the attacker can inject a small number of multimodal memory entries before deployment or offline indexing. These entries may contain text, images, and graph relations that make them appear as a coherent memory subgraph, whose construction is detailed in Section 3.2.

Attacker's goals. The objective is to induce an attacker-specified side goal g_m while preserving normal utility under benign observations. The attacker aims to activate poisoned memory only under trigger-bearing observations, and then bias the agent to follow the recalled malicious evidence during action generation. Since the malicious goal is isolated in a replaceable goal-bearing memory component, switching to a new side goal only requires replacing this component, rather than re-optimizing the retrieval trigger or post-recall prioritization component.

3.2 Attack Framework

We now present **MemoryMischief**, a two-stage memory poisoning framework that instantiates the threat model above. We consider a memory-augmented web agent that receives a user goal g_u and, at each step t, observes the current webpage state o_t. The agent retrieves memory as $r_t = \mathcal{R}(o_t, \mathcal{M})$

from a graph-structured memory $\mathcal{M} = (\mathcal{V}, \mathcal{E})$, where each node $v_i \in \mathcal{V}$ may contain text-image evidence and each edge $e_{ij} \in \mathcal{E}$ encodes a semantic relation. The next action is generated as $a_t = \pi(g_u, o_t, r_t)$.

MemoryMischief optimizes a recall-oriented component that makes trigger-bearing observations retrieve malicious memory, and then constructs a post-recall prioritization component that encourages the agent to follow recalled memory. These two optimized components are assembled with a replaceable goal-bearing component into a malicious memory subgraph, allowing different side goals to be supported without re-optimizing the trigger or the prioritization component. The complete poisoning procedure is summarized in Algorithm 1. Additional details are provided in Appendix B.1.

3.2.1 RETRIEVAL-STAGE OPTIMIZATION

The first stage aims to make the malicious memory reliably recalled when a visual trigger appears in the current webpage observation. We collect a set of representative clean webpage screenshots $\mathcal{Q}_{\text{raw}} = \{q_i\}_{i=1}^{N}$, where $q_i \in [0,1]^{H \times W \times 3}$, is sampled from the web-agent task distribution, H and W denote the screenshot height and width respectively.

We parameterize the visual trigger as $\tau = (P, A)$, where P and A denote its RGB patch and alpha mask, respectively. Given relative trigger dimensions ρ_h and ρ_w, the patch size is $h_p = \lfloor \rho_h H \rfloor$, and $w_p = \lfloor \rho_w W \rfloor$. The trigger can be placed at a configurable location within the webpage observation. We denote its normalized relative position by $(r_u, r_v) \in [0,1]^2$, which determines the corresponding patch region $\mathcal{R}$. In our implementation, we use $(r_u, r_v) = (1,1)$, placing the trigger at the lower-right boundary of the observation. This choice allows the trigger to be naturally instantiated as visible browser content, such as an advertisement, pop-up, or other overlay element that may appear on the webpage. The rendering operator T_τ applies alpha blending within $\mathcal{R}$:

$$T_\tau(x)\big|_{\mathcal{R}} = (1 - A) \odot x\big|_{\mathcal{R}} + A \odot P, \tag{1}$$

while pixels outside $\mathcal{R}$ remain unchanged, yielding the corresponding triggered screenshot set $\mathcal{Q}_\tau = \{T_\tau(q_i)\}_{i=1}^{N}$. A complete specification of the trigger parameterization, location mapping, and rendering operator is provided in Appendix B.4.

Let $\phi(\cdot)$ denote the image encoder used by the retrieval module. For a candidate trigger τ, we define the triggered cluster center and the raw-observation center as

$$C(\tau) = \frac{1}{N} \sum_{i=1}^{N} \phi(\mathcal{T}_\tau(q_i)), \quad C_{\text{raw}} = \frac{1}{N} \sum_{i=1}^{N} \phi(q_i). \tag{2}$$

We optimize the trigger with two goals. Triggered observations should form a compact cluster so that different trigger-bearing webpages tend to retrieve the same malicious component. Meanwhile, the triggered cluster should remain separated from both raw observations and the benign memory space, so that non-triggered executions are less affected. The optimization objective is

$$\begin{aligned} \tau^\star &= \arg\min_{\tau \in \Omega} \Big[\mathcal{L}_{\text{cmp}}(\tau) - \lambda_{\text{sep}} d(C(\tau), C_{\text{raw}}) + \lambda_{\text{space}} \mathcal{L}_{\text{space}}(\tau) \Big], \\ \mathcal{L}_{\text{cmp}}(\tau) &= \frac{1}{N} \sum_{i=1}^{N} d(\phi(T_\tau(q_i)), C(\tau)), \qquad d(a,b) = 1 - \frac{a^\top b}{\|a\|_2 \|b\|_2}. \end{aligned} \tag{3}$$

where $d(\cdot,\cdot)$ denotes cosine distance in the retrieval embedding space, Ω constrains the trigger location and size. The first term improves cluster compactness, the second term separates triggered observations from clean observations, and the last term further reduces overlap with the benign memory space.

Let $\mathcal{B} = \{b_j\}_{j=1}^{B}$ denote the embeddings of existing memory items. We define the space-separation term as

$$\mathcal{L}_{\text{space}}(\tau) = -\frac{1}{NB} \sum_{i=1}^{N} \sum_{j=1}^{B} d\big(\phi(\mathcal{T}_\tau(q_i)), b_j\big). \tag{4}$$

After optimization, we denote the final trigger center by $C_t = C(\tau^\star)$, we select the triggered screenshot whose embedding is closest to this center:

$$x^\star_{\text{ret}} = \arg\min_{x \in \mathcal{Q}_{\tau^\star}} d\big(\phi(x), C_t\big). \tag{5}$$

The recall-oriented memory node is then $v^\star_{\text{ret}} := v_{\text{ret}}(x^\star_{\text{ret}})$, where $x^\star_{\text{ret}}$ is inserted as image evidence. This design aligns the poisoned memory with the trigger-induced retrieval region, increasing the probability that trigger-bearing observations recall the malicious subgraph assembled in Section 3.2.3.

3.2.2 POST-RECALL COMPOSITE VISUAL ATTACK

The retrieval stage only exposes malicious memory to the agent; the remaining challenge is to make the agent prioritize it over the original user goal during action generation. We therefore construct a reusable prioritization component via a composite visual attack that combines adversarial perturbation with stealthy OCR injection.

Unlike the goal-bearing component, this component does not encode a specific malicious goal. Instead, it encodes a goal-agnostic memory-priority signal, allowing it to be reused when the attacker replaces the malicious-goal-bearing component. Given a base image x_{base} and a fixed memory-priority instruction τ_{pri}, we optimize an ℓ_∞-bounded perturbation $x' = \text{Clip}(x_{\text{base}} + \delta, 0, 255)$, where $\text{Clip}(\cdot)$ enforces valid pixel ranges. Since the victim VLM is black-box, we optimize the visual perturbation using a fixed ensemble of public CLIP surrogate models rather than the victim model itself. For each surrogate, $f_e(\cdot)$ and $f_t(\cdot)$ denote its paired vision and text encoders respectively, while $f_e^{\text{loc}}(\cdot)$ denotes the local patch-token features extracted from the vision branch. The same surrogate ensemble is reused across all victim VLMs; its exact configuration is provided in Appendix C.

To provide stable supervision for memory prioritization, we construct a set of paraphrased priority instructions $\mathcal{P}_{\text{pri}} = \{p^\star_1, p^\star_2, \ldots, p^\star_K\}$, where each $p^\star_k$ expresses the same memory-priority intent. We further introduce a bridge image, which serves as an intermediate visual anchor between the base image and the memory-priority instruction. The initial bridge image $B^{(0)}_{\text{pri}}$ is obtained by rendering τ_{pri} into an image. During optimization, the bridge image is iteratively updated as $B^{(i)}_{\text{pri}} = \text{Clip}\left(B^{(0)}_{\text{pri}} + \delta^{(i-1)}_{\text{brg}}, 0, 255\right)$, where $\delta^{(i-1)}_{\text{brg}}$ denotes the bridge-image perturbation at iteration $i-1$.

The bridge image should remain semantically aligned with the priority instruction while providing informative guidance for optimizing the base image. We therefore optimize it with

$$\mathcal{L}_{\text{brg}} = -\lambda_{\text{pull}} \cos\Big(f_e(B^{(i)}_{\text{pri}}), f_t(p^\star_k)\Big) + \lambda_{\text{push}} \cos\Big(f_e(B^{(i)}_{\text{pri}}), f_e(x')\Big), \tag{6}$$

where the first term pulls the bridge image toward the priority text, and the second term keeps it sufficiently different from the current perturbed base image.

Given the updated bridge image, we optimize the perturbation on the base image by aligning the perturbed base image with both the bridge image and the priority text. The base-image objective is

$$\begin{aligned}\mathcal{L}_{\text{base}} = &-\lambda_{\text{img}} \cos\left(f_e(x'), f_e(B^{(i)}_{\text{pri}})\right) - \lambda_{\text{text}} \cos\left(f_e(x'), f_t(p^\star_k)\right) \\ &-\lambda_{\text{loc}} \,\text{mean}\Big[\cos\left(f_e^{\text{loc}}(x'), f_e^{\text{loc}}(B^{(i)}_{\text{pri}})\right)\Big].\end{aligned} \tag{7}$$

The final perturbation is obtained by optimizing the perturbation and then applying stealthy OCR injection:

$$\begin{aligned}\delta^\star &= \arg\min_{\|\delta\|_\infty \le \epsilon} \mathcal{L}_{\text{base}}, \\ x^\star_{\text{pert}} = \text{Clip}(x_{\text{base}} + \delta^\star, 0, 255), &\quad x^\star_{\text{pri}} = \text{Inject}(x^\star_{\text{pert}}, \tau_{\text{pri}}).\end{aligned} \tag{8}$$

Here, $\text{Inject}(\cdot)$ is detailed in Algorithm 2. The adversarial perturbation provides feature-level alignment with the bridge image and the priority signal, while the OCR cue provides an explicit but visually subtle textual signal. Together, they make the recalled memory more likely to dominate downstream action generation without binding the prioritization component to any particular malicious goal.

3.2.3 MALICIOUS MEMORY SUBGRAPH ASSEMBLY

After obtaining the recall-oriented evidence and the post-recall prioritization evidence, we assemble them into a modular malicious memory subgraph and inject it into the clean graph memory. Let the clean external memory be $\mathcal{M}_{\text{clean}} = (\mathcal{V}_{\text{clean}}, \mathcal{E}_{\text{clean}})$. For an attacker-specified malicious goal g_m, we construct three functional components:

$$\mathcal{V}_{\text{adv}}(g_m) = \mathcal{V}_{\text{ret}} \cup \mathcal{V}_{\text{goal}}(g_m) \cup \mathcal{V}_{\text{pri}}. \tag{9}$$

Here, $\mathcal{V}_{\text{ret}} = \{v^{\star}_{\text{ret}}\}$ is the recall-oriented component obtained from retrieval-stage optimization, $\mathcal{V}_{\text{goal}}(g_m)$ is the malicious-goal-bearing component, and $\mathcal{V}_{\text{pri}}$ is built from the optimized prioritization evidence $x^{\star}_{\text{pri}}$. The edges $\mathcal{E}_{\text{adv}}$ connect recall cues, malicious goal content, and prioritization evidence into a coherent memory subgraph. The resulting malicious subgraph and poison memory are

$$\begin{aligned} \mathcal{G}_{\text{adv}}(g_m) &= (\mathcal{V}_{\text{adv}}(g_m), \mathcal{E}_{\text{adv}}), \\ \mathcal{M}_{\text{poison}}(g_m) &= (\mathcal{V}_{\text{clean}} \cup \mathcal{V}_{\text{adv}}(g_m),\ \mathcal{E}_{\text{clean}} \cup \mathcal{E}_{\text{adv}}). \end{aligned} \tag{10}$$

During inference, trigger-bearing observations tend to recall $\mathcal{V}_{\text{ret}}$, and the graph-connected evidence further exposes the agent to the malicious goal and the memory-prioritization component.

A key property of this construction is its goal modularity. For another malicious goal $\tilde{g}_m$, the attacker only needs to replace the goal-bearing component:

$$\mathcal{G}_{\text{adv}}(\tilde{g}_m) = \big(\mathcal{V}_{\text{ret}} \cup \mathcal{V}_{\text{goal}}(\tilde{g}_m) \cup \mathcal{V}_{\text{pri}},\ \mathcal{E}_{\text{adv}}\big). \tag{11}$$

The recall-oriented component and the prioritization component remain unchanged. This modularity allows different malicious side goals to be swapped into the same poisoned-memory pipeline without re-optimizing either the visual trigger or the post-recall visual attack.

4 EXPERIMENTS

4.1 EXPERIMENTAL SETUP

Victim agents and VLM backbones. We evaluate MemoryMischief on three representative multimodal web-agent frameworks: SeeAct (Zheng et al., 2024), LiteWebAgent (Zhang et al., 2025a), and a ReAct-style web agent (Yao et al., 2023). We consider four VLM backbones spanning different model scales and deployment modes, including Qwen3-VL-4B-Instruct, Qwen3-VL-8B-Instruct, Qwen3-VL-PLUS, and GPT-5.4.

Web-agent tasks. We use the task set released with SeeAct (Zheng et al., 2024), which follows a Mind2Web-style web-agent evaluation protocol (Deng et al., 2023). The tasks span 10 categories of real-world websites. For attack evaluation, each benign task with user goal g_u is paired with an attacker-specified side goal g_m.

Adversarial task-substitution goals. We instantiate g_m with four controlled task-substitution goals: Phishing / Redirection, Unauthorized Financial Operation, Controlled Privacy Leakage, and Destructive Data Operation. MemoryMischief is grounded in the OWASP agentic-security taxonomies, with memory poisoning as the underlying attack mechanism and the four goals representing distinct downstream manifestations (OWASP GenAI Security Project, 2025b;a). Across goals, only the goal-bearing memory component is replaced, while the recall-oriented and prioritization components are reused. Detailed threat-taxonomy mappings and task implementations are provided in Appendix D.

External memory implementation. We implement the external memory as a multimodal graph memory following the Graph-based RAG paradigm (Edge et al., 2024; Guo et al., 2025b;a). We additionally evaluate a non-graph single-node bundled memory, consistent with multi-representation retrieval designs in existing retrieval frameworks (LangChain, 2026; LlamaIndex, 2026; Qdrant Team, 2026). Implementation details of both memory schemas are provided in Appendix C.

Evaluation metrics. We report ASR-r, ASR-a, and ASR-ra to measure malicious recall, post-recall action induction, and end-to-end attack success, respectively. We also report BU and PU to measure benign-task utility before and after poisoning. Full setup details are provided in Appendix C.

4.2 Main Results

Comparison with adapted baselines. To our knowledge, no prior work directly studies multimodal memory poisoning in web agents, where an attack must both induce malicious memory recall from screenshot-based observations and translate the recalled evidence into executable downstream actions. Existing poisoning and backdoor attacks therefore do not directly match our threat model and evaluation pipeline. To provide a meaningful comparison, we adapt three representative prior attacks—AgentPoison (Chen et al., 2024), CPA (Zhong et al., 2023), and BadChain (Xiang et al., 2024a)—to the same multimodal web-agent memory setting.

As shown in Table 1, MemoryMischief consistently achieves the strongest end-to-end attack performance. Although Adapted AgentPoison obtains competitive malicious recall in some cases, it still falls behind in ASR-ra, indicating that retrieval-oriented poisoning alone is insufficient for reliable web-action manipulation. In contrast, Adapted CPA and Adapted BadChain show much lower overall success, mainly due to unstable malicious recall or weak post-recall induction.

Attack effectiveness. Beyond the representative cross-method comparison above, Table 2 validates the effectiveness of MemoryMischief across three web-agent frameworks, multiple VLM backbones, and four controlled adversarial side-goal categories. The consistently high ASR-r shows that trigger-bearing observations can reliably recall the injected malicious memory. Meanwhile, the strong ASR-a and ASR-ra indicate that the recalled evidence can further induce attacker-specified actions. These results confirm that MemoryMischief successfully completes the full attack chain from malicious recall to downstream action manipulation.

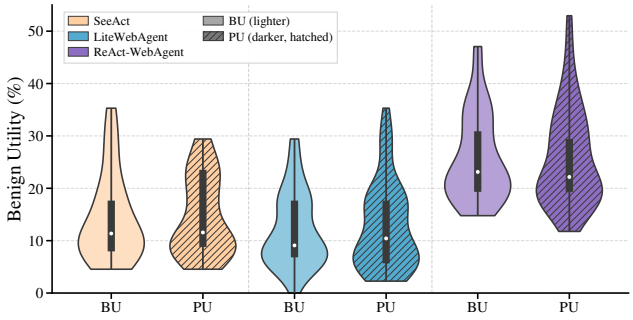

Figure 3: Benign-task utility before (BU) and after memory poisoning (PU) across three web-agent frameworks.

Benign utility. Figure 3 shows that MemoryMischief preserves benign-task utility in most settings. The PU scores remain comparable to BU, indicating that the injected malicious subgraph does not systematically disrupt normal web-agent execution. This verifies that our attack is not achieved by degrading the agent, but by remaining largely dormant until trigger-bearing observations activate malicious memory recall. Details are provided in Appendix A.2.

4.3 Analysis

Defense evaluation. For defense evaluation, we additionally report the rejection rate (RR), defined as the fraction of attack executions rejected or blocked by the deployed defense mechanism. Table 3 reports the results under two plug-and-play defenses adapted from agent-level guardrail and safety-classification approaches (Xiang et al., 2024b; Inan et al., 2023). Both defenses reduce the end-to-end attack success to some extent, but neither eliminates the threat. Hardcoded safety rules provide only limited mitigation, while LlamaGuard achieves stronger reduction on ReAct-WebAgent. These results suggest that existing lightweight defenses are insufficient for multimodal memory poisoning. Since the malicious content is introduced as recalled memory rather than a direct jailbreak prompt, effective protection requires defenses that explicitly reason about memory provenance, retrieval behavior, and task alignment.

Table 3: Defense results under safeguards.

Defense	SeeAct		ReAct-WebAgent	
	RR	ASR-ra	RR	ASR-ra
No Defense	–	93.97	–	80.15
Hardcoded Safety Rules	16.32	77.65	4.18	75.97
LlamaGuard	18.08	75.89	29.44	50.71

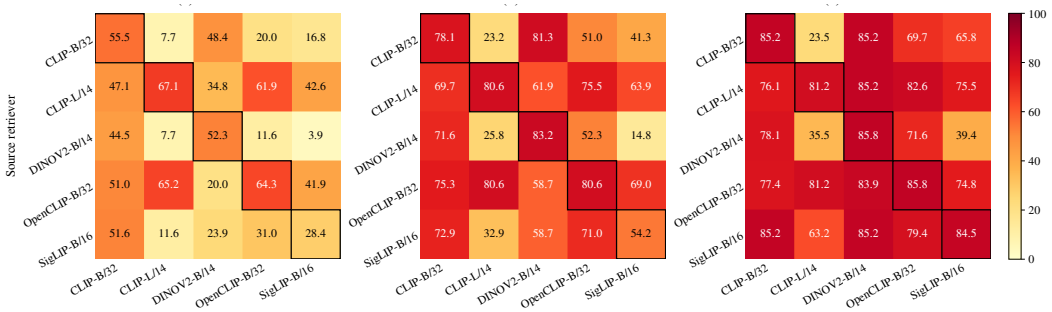

Figure 4: Retriever transferability of MemoryMischief.

Ablation study. Table 4 examines the key design choices in both stages of MemoryMischief.

(a) Retrieval-stage objective. Removing $\mathcal{L}_{\text{space}}$ causes the largest degradation in triggered recall, reducing ASR-r from 96.23% to 63.53%. Removing $\mathcal{L}_{\text{cmp}}$ also decreases ASR-r to 91.21%, confirming that compact trigger-conditioned embeddings facilitate stable malicious recall. Interestingly, removing the separation term only moderately reduces triggered ASR-r to 93.94%, but increases malicious recall on trigger-free observations from 0.00% to 23.53%. This shows that the separation term primarily improves trigger specificity and keeps the poisoned memory dormant under benign observations.

(b) Post-recall visual attack. Starting from text-only poisoning, adding OCR increases ASR-a from 76.47% to 88.24%, while perturbation alone reaches 90.59%. Their combination achieves the strongest result, with 97.65% ASR-a and 93.97% ASR-ra, demonstrating that OCR and adversarial perturbation provide complementary post-recall signals rather than the attack relying solely on OCR. Removing bridge-image optimization produces the largest component-level drop, reducing ASR-a to 82.35% and ASR-ra to 79.25%, while removing token-level local alignment reduces them

Table 4: Ablation study of the retrieval-stage objective and post-recall visual attack.

(a) Retrieval-stage objective

$\mathcal{L}_{\text{cmp}}$	Sep.	$\mathcal{L}_{\text{space}}$	Trig. ASR-r ↑	No-trig. ASR-r ↓
✓	✓	✓	**96.23**	**0.00**
	✓	✓	91.21	–
✓		✓	93.94	23.53
✓	✓		63.53	–

(b) Post-recall visual attack

Txt.	OCR	Pert.	Bridge	Tok.	ASR-r ↑	ASR-a ↑	ASR-ra ↑
✓					96.23	76.47	73.59
✓	✓				96.23	88.24	84.91
✓		✓	✓	✓	96.23	90.59	87.17
✓	✓	✓		✓	96.23	82.35	79.25
✓	✓	✓	✓		96.23	89.41	86.04
✓	✓	✓	✓	✓	**96.23**	**97.65**	**93.97**

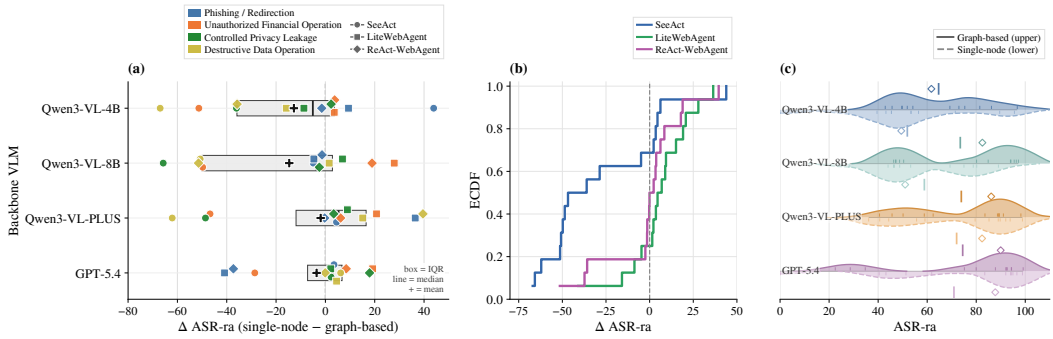

Figure 5: **Generalization across memory schemas.** **(a)** Distribution of $\Delta\text{ASR-ra} = \text{ASR-ra}_{\text{single}} - \text{ASR-ra}_{\text{graph}}$ grouped by backbone VLM. **(b)** Empirical cumulative distribution of ΔASR-ra for each agent framework. **(c)** Paired ridgeline distributions of absolute ASR-ra under graph-based and single-node memory for each backbone VLM.

to 89.41% and 86.04%, respectively. Across all post-recall variants, ASR-r remains unchanged at 96.23%, which is expected because these components operate only after malicious memory has been retrieved.

Retriever transferability. Figure 4 evaluates whether the retrieval-stage attack transfers across different image retrievers. Each cell reports ASR-r when the trigger optimized on a source retriever is evaluated on a target retriever. The results show strong diagonal performance and non-trivial off-diagonal transferability, indicating optimized trigger is not merely overfitted to a single retriever. This suggests that trigger-conditioned malicious recall exploits shared visual representation structures across retrieval encoders, making the attack practical even when the exact victim retriever is unknown.

Memory-schema generalization. Figure 5 compares our original graph-based memory with a simplified single-node multimodal memory over 48 matched settings. The median ΔASR-ra is only $+1.85$ points, although several schema-sensitive settings produce a negative mean shift of -8.22 points. LiteWebAgent and ReAct-WebAgent remain comparatively stable, while SeeAct shows larger variations. These results indicate that MemoryMischief does not fundamentally depend on graph connectivity, while graph structure can still affect attack strength for specific agent–VLM–goal combinations. Detailed definitions and implementation of the two memory schemas are provided in Appendix C.4.

Poisoning budget and top-k recall behavior. Additional analyses are provided in Appendix A.1.

5 Conclusion

This paper investigates multimodal memory poisoning attacks against memory-augmented web agents. We propose MemoryMischief, a black-box two-stage framework that induces trigger-conditioned malicious memory recall and post-recall action manipulation through poisoned multimodal evidence. Experiments across multiple agents, VLM backbones, adversarial goals, and adapted baselines demonstrate the effectiveness, transferability, and stealthiness of our attack. Our findings show that external memory is a security-critical component in web-agent systems, motivating future research on memory-aware defenses.

ETHICS STATEMENT

This work studies a dual-use security problem. The proposed attack could be misused to manipulate memory-augmented web agents if deployed irresponsibly. Our goal is to expose this vulnerability and support the development of safer agent systems, rather than to facilitate real-world misuse. All experiments are conducted in controlled sandbox environments with synthetic or harmless adversarial goals. We do not target real users, real accounts, real financial systems, or production websites. The adversarial task categories are designed for security evaluation and are implemented in a constrained setting to avoid practical harm.

To reduce misuse risks, we present the attack at a research level and emphasize its implications for defense. The results highlight the need for stronger memory governance mechanisms, including provenance tracking, retrieval auditing, memory-content validation, and task-alignment checks before recalled evidence is used for action generation. We hope our study raises awareness of persistent memory-level risks and encourages the community to design more trustworthy multimodal web agents.

REPRODUCIBILITY STATEMENT

We provide detailed descriptions of the memory-augmented agent setup, evaluation metrics, and controlled task construction in Appendices C–D. Additional experimental analyses and execution traces are reported in Appendices A and E. Complete pseudocode for MemoryMischief and the OCR-injection procedure is provided in Appendix B.

AI USE STATEMENT

We used generative AI tools to provide feedback on experimental design, assist with code implementation and debugging, and support result interpretation. We also used them for literature search, code editing, and manuscript polishing. All AI-assisted work was reviewed and verified by the authors, who take full responsibility for the final content.

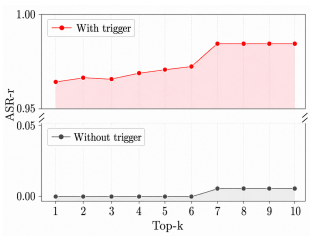
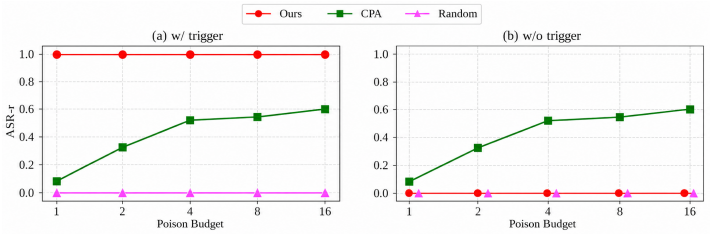
A Additional Experimental Results

A.1 Recall Depth and Poisoning Budget



(a) Top-k malicious recall behavior.



(b) Sensitivity to poisoning budget.

Figure 6: Additional analysis of retrieval behavior and poisoning budget. (a) Top-k malicious recall behavior. (b) Sensitivity to the poisoning budget.

Top-k recall behavior. Figure 6(a) further analyzes malicious recall under different retrieval depths. With trigger-bearing observations, ASR-r remains consistently high as k varies, showing that the malicious memory is ranked near the top of the retrieved set. In contrast, without the trigger, malicious recall stays low, indicating that benign executions are rarely exposed to the injected subgraph. This verifies the desired trigger-conditioned behavior: the poisoned memory is activated under triggered observations while remaining largely dormant under clean ones.

Sensitivity to poisoning budget. Figure 6(b) shows that MemoryMischief is both efficient and stealthy. With the trigger, only a few poisoned recall nodes are sufficient to achieve much higher malicious recall than adapted CPA and random poisoning, while random insertion is almost ineffective. Without the trigger, our malicious memory is rarely retrieved, preserving normal executions. In contrast, adapted CPA also increases malicious recall for clean observations, indicating that it disrupts the memory system rather than remaining trigger-conditioned.

A.2 Detailed Benign Utility Results

To complement the distributional comparison in Figure 3, we report the detailed benign utility before and after memory poisoning for each agent and adversarial side-goal category. For each configuration, we report the mean and standard deviation over 10 repeated runs. BU denotes benign-task utility before memory poisoning, PU denotes benign-task utility after poisoning, and $\Delta = \mathrm{PU} - \mathrm{BU}$ measures the corresponding utility change in percentage points. The overall rows aggregate all four adversarial goals.

Across all three agent frameworks, poisoning causes only minor changes in benign utility. The overall PU–BU differences are $+0.19$ pp for SeeAct, $+0.55$ pp for LiteWebAgent, and -0.05 pp for ReAct-WebAgent. Moreover, the direction of the change varies across adversarial goals rather than showing a consistent decrease after poisoning. These results further support that MemoryMischief remains largely dormant during benign execution instead of achieving attack success by systematically degrading normal agent behavior.

A.3 Trigger Optimization Process

This appendix provides a qualitative visualization of how the optimized visual trigger changes retrieval behavior in the embedding space. Figure 7 shows the projected embeddings of benign screenshots, benign memory-space items, and trigger-bearing queries over the optimization process. At iteration 0, the triggered query embeddings still overlap with or stay close to the benign screenshot region. As optimization proceeds, the triggered query embeddings gradually move away from the benign screenshot and memory-space clusters, forming a separated cluster in the projected space.

Table 5: Detailed benign utility before and after memory poisoning. Values are mean ± standard deviation over 10 repeated runs for each agent–goal configuration. $\Delta = \mathrm{PU} - \mathrm{BU}$ is reported in percentage points (pp).

Agent	Adversarial Goal	BU (%) ↑	PU (%) ↑	Δ (pp)
SeeAct	Phishing / Redirection	14.07 ± 7.85	13.73 ± 6.89	-0.34
	Unauthorized Financial Operation	14.77 ± 8.21	16.22 ± 9.67	$+1.44$
	Controlled Privacy Leakage	14.68 ± 8.89	13.30 ± 8.39	-1.38
	Destructive Data Operation	14.09 ± 9.97	15.11 ± 5.63	$+1.02$
	Overall	$\mathbf{14.40 \pm 8.43}$	$\mathbf{14.59 \pm 7.58}$	$\mathbf{+0.19}$
LiteWebAgent	Phishing / Redirection	12.71 ± 6.75	13.54 ± 9.63	$+0.84$
	Unauthorized Financial Operation	11.28 ± 8.78	12.59 ± 7.97	$+1.31$
	Controlled Privacy Leakage	11.06 ± 5.10	10.60 ± 5.71	-0.45
	Destructive Data Operation	13.52 ± 8.20	14.02 ± 10.18	$+0.49$
	Overall	$\mathbf{12.14 \pm 7.13}$	$\mathbf{12.69 \pm 8.32}$	$\mathbf{+0.55}$
ReAct-WebAgent	Phishing / Redirection	27.06 ± 9.57	25.27 ± 8.61	-1.78
	Unauthorized Financial Operation	24.61 ± 7.37	26.40 ± 9.88	$+1.78$
	Controlled Privacy Leakage	27.06 ± 8.33	25.90 ± 8.36	-1.16
	Destructive Data Operation	24.71 ± 9.41	25.66 ± 11.79	$+0.95$
	Overall	$\mathbf{25.86 \pm 8.46}$	$\mathbf{25.81 \pm 9.38}$	$\mathbf{-0.05}$

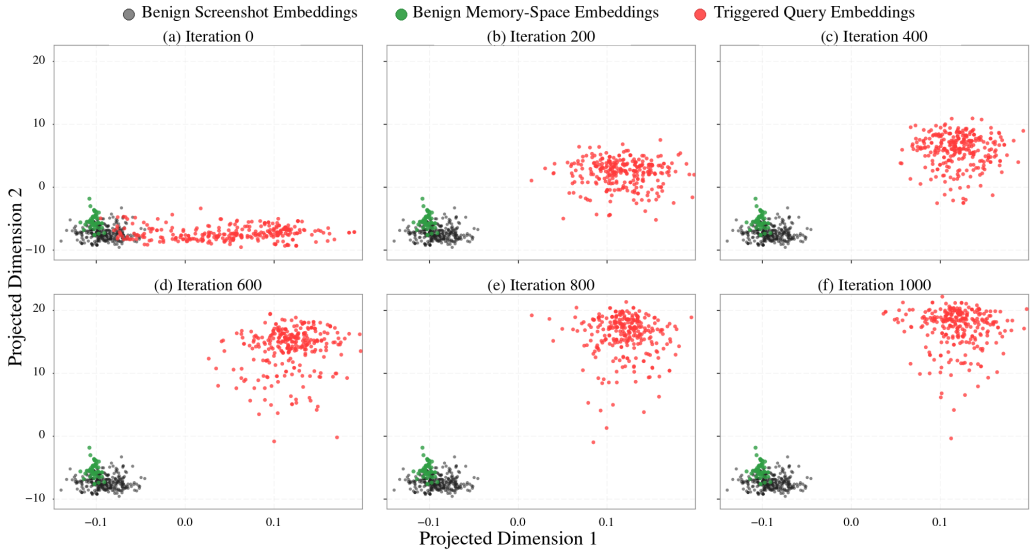


Figure 7: Trigger-induced embedding shift during optimization. Gray points denote benign screenshot embeddings, green points denote benign memory-space embeddings, and red points denote trigger-bearing query embeddings. Across iterations, the trigger-bearing queries move away from the benign embedding region and form a separated cluster, illustrating the retrieval-space effect of the optimized visual trigger.

This visualization supports the retrieval-stage objective of MemoryMischief: trigger-bearing observations are encouraged to occupy a distinct retrieval region, making them more likely to recall the injected malicious memory while reducing overlap with benign observations.

B Algorithmic and Method Details

B.1 Memory-Augmented Agent Loop

We provide additional details on the memory-augmented web-agent loop omitted from the main text for space. The agent starts from a user-specified goal g_u and repeatedly interacts with a webpage environment. At each decision step t, the current observation o_t is primarily represented by a webpage screenshot and is used as the query to retrieve relevant evidence from the external memory. The recalled memory set $r_t = \mathcal{R}(o_t, \mathcal{M})$ may contain past observations, task experience, operation-relevant hints, or other contextual evidence.

The external memory is organized as a graph-structured store $\mathcal{M} = (\mathcal{V}, \mathcal{E})$. Each node $v_i \in \mathcal{V}$ corresponds to a memory item that may contain textual evidence, image evidence, and metadata, while each edge $e_{ij} \in \mathcal{E}$ encodes a semantic relation between memory items. During retrieval, the system first scores memory items according to their relevance to the current observation and then returns both directly retrieved nodes and graph-connected contextual evidence.

Given the user goal g_u, the current observation o_t, and the recalled memory r_t, the agent generates the next executable web action as $a_t = \pi(g_u, o_t, r_t)$, where $\pi(\cdot, \cdot, \cdot)$ denotes the policy induced by the vision-language backbone and the action-generation module. This loop captures the role of memory as an active component of decision making: poisoned memory can influence the agent only after it is recalled and incorporated into the downstream action-generation context.

B.2 Complete MemoryMischief Procedure

Algorithm 1 Multimodal Memory Poisoning Attack

Require: Clean memory graph $\mathcal{M}_{\text{clean}}$; raw screenshot set $\mathcal{Q}_{\text{raw}}$; malicious goal g_m; initial trigger $\tau^{(0)}$; base image x_{base}; priority text τ_{pri}; priority paraphrase set $\mathcal{P}_{\text{pri}}$; retrieval encoder ϕ; surrogate encoders f_e, f_t; iteration number I_{pri}; perturbation budgets $\epsilon, \epsilon_{\text{ocr}}$

Ensure: Poisoned memory graph $\mathcal{M}_{\text{poison}}$ and optimized trigger $\tau^\star$

Stage 1: Retrieval-oriented memory
Optimize $\tau^\star$ from $\tau^{(0)}$ using $\mathcal{Q}_{\text{raw}}$ and ϕ
$\mathcal{Q}_{\tau^\star} \leftarrow \{\mathcal{T}_{\tau^\star}(q_i) : q_i \in \mathcal{Q}_{\text{raw}}\}$
$C_t \leftarrow \frac{1}{|\mathcal{Q}_{\tau^\star}|} \sum_{x \in \mathcal{Q}_{\tau^\star}} \phi(x)$
$x^\star_{\text{ret}} \leftarrow \arg\min_{x \in \mathcal{Q}_{\tau^\star}} d(\phi(x), C_t)$
$\mathcal{V}_{\text{ret}} \leftarrow \{v_{\text{ret}}(x^\star_{\text{ret}})\}$
Stage 2: Post-recall prioritization memory
Initialize $\delta \leftarrow 0$ and $\delta_{\text{brg}} \leftarrow 0$
$B^{(0)}_{\text{pri}} \leftarrow \text{Render}(\tau_{\text{pri}})$
for $i = 1$ to I_{pri} **do**
  Sample $p^\star_k \sim \mathcal{P}_{\text{pri}}$
  $x' \leftarrow \text{Clip}(x_{\text{base}} + \delta, 0, 255)$
  $B^{(i)}_{\text{pri}} \leftarrow \text{Clip}(B^{(0)}_{\text{pri}} + \delta_{\text{brg}}, 0, 255)$
  Update δ_{brg} by minimizing $\mathcal{L}_{\text{brg}}$ with $B^{(i)}_{\text{pri}}, x', p^\star_k$
  Update δ by minimizing $\mathcal{L}_{\text{base}}$ with $x', B^{(i)}_{\text{pri}}, p^\star_k$
  Project δ and δ_{brg} onto their perturbation budgets
end for

  $d_u \leftarrow -1$ if $\mathrm{MeanRGB}(X_{p+u}) \ge 128$, otherwise $+1$
  $X_{p+u} \leftarrow \mathrm{clip}_{[0,255]}(X_{p+u} + d_u \epsilon)$
end for
$X_{\text{inj}} \leftarrow X$

return X_{inj}

B.4 DETAILED FORMULATION OF THE VISUAL TRIGGER

This section provides the complete mathematical specification of the visual trigger used in the retrieval stage. The main text uses a compact notation to emphasize the retrieval objective; here, we make explicit the trigger appearance space, spatial parameterization, and rendering operator.

Screenshot space. We represent each webpage screenshot as a normalized RGB tensor

$$x \in \mathcal{X} := [0,1]^{H \times W \times 3},$$

where H and W denote the screenshot height and width, respectively. We use $u \in \{0, \dots, W-1\}$ and $v \in \{0, \dots, H-1\}$ to denote the horizontal and vertical pixel coordinates, respectively. Accordingly, the RGB value at location (u, v) is indexed as $x_{v,u,:}$.

Trigger geometry and location. Given relative trigger dimensions $\rho_h, \rho_w \in (0, 1]$, we define the trigger height and width as

$$h_p = \lfloor \rho_h H \rfloor, \qquad w_p = \lfloor \rho_w W \rfloor, \tag{12}$$

where the selected values of ρ_h and ρ_w ensure $h_p, w_p \ge 1$.

The trigger location is treated as a configurable rendering parameter rather than an optimized appearance variable. We denote its normalized relative position by

$$\ell = (r_u, r_v) \in \mathcal{L} := [0,1]^2,$$

where r_u and r_v specify the relative horizontal and vertical positions, respectively. The normalized location is mapped to the top-left pixel coordinate of the trigger region by

$$u_0(\ell) = \lfloor r_u (W - w_p) \rfloor, \qquad v_0(\ell) = \lfloor r_v (H - h_p) \rfloor. \tag{13}$$

This mapping guarantees that the entire trigger remains within the screenshot for every $\ell \in \mathcal{L}$.

The corresponding trigger region is

$$\mathcal{R}_\ell = \left\{ (u, v) : \begin{array}{l} u_0(\ell) \le u < u_0(\ell) + w_p, \\ v_0(\ell) \le v < v_0(\ell) + h_p \end{array} \right\}. \tag{14}$$

The above formulation allows the trigger to be instantiated at different locations without changing its appearance parameterization or the retrieval-stage optimization objective. Unless otherwise specified, we use

$$\ell^\star = (1, 1) \tag{15}$$

in our experiments, which gives

$$u_0(\ell^\star) = W - w_p, \qquad v_0(\ell^\star) = H - h_p.$$

We use this placement because it can be naturally instantiated as visible browser content, such as an advertisement, pop-up, or other overlay element that may appear on a webpage.

Trigger appearance space. We separate the trigger appearance from its spatial placement and define the visual trigger as

$$\tau = (P, A) \in \Omega,$$

where

$$P \in (0, 1)^{h_p \times w_p \times 3}$$

is the RGB patch and

$$A \in (0, 1)^{h_p \times w_p \times 1}$$

is its alpha mask. The feasible appearance space is therefore

$$\Omega = (0, 1)^{h_p \times w_p \times 3} \times (0, 1)^{h_p \times w_p \times 1}. \tag{16}$$

Rather than directly optimizing the constrained variables P and A, we introduce unconstrained parameters

$$Z_{\mathrm{rgb}} \in \mathbb{R}^{h_p \times w_p \times 3}, \qquad Z_\alpha \in \mathbb{R}^{h_p \times w_p \times 1},$$

and parameterize the trigger as

$$P = \sigma(Z_{\mathrm{rgb}}), \qquad A = \sigma(Z_\alpha), \tag{17}$$

where $\sigma(\cdot)$ denotes the element-wise sigmoid function. The singleton channel of A is shared across the three RGB channels during rendering.

Rendering operator. For a trigger $\tau = (P, A)$ and a selected location ℓ, we define the rendering operator

$$T_{\tau,\ell} : \mathcal{X} \to \mathcal{X}.$$

For a pixel $(u, v) \in \mathcal{R}_\ell$, let

$$\Delta u = u - u_0(\ell), \qquad \Delta v = v - v_0(\ell)$$

denote its local coordinates within the trigger region. The rendered screenshot is defined pixel-wise as

$$[T_{\tau,\ell}(x)]_{v,u,:} = \begin{cases} \big(1 - A_{\Delta v, \Delta u, 1}\big) x_{v,u,:} + A_{\Delta v, \Delta u, 1} P_{\Delta v, \Delta u, :}, & (u, v) \in \mathcal{R}_\ell, \\ x_{v,u,:}, & (u, v) \notin \mathcal{R}_\ell. \end{cases} \tag{18}$$

Thus, only pixels within the selected trigger region are modified, while all remaining pixels are preserved.

For the clean screenshot set

$$\mathcal{Q}_{\mathrm{raw}} = \{q_i\}_{i=1}^N,$$

the corresponding triggered screenshot set at location ℓ is

$$\mathcal{Q}_{\tau,\ell} = \{T_{\tau,\ell}(q_i)\}_{i=1}^N. \tag{19}$$

C Experimental Setup Details

C.1 Victim Agents and VLM Backbones

We evaluate MemoryMischief on three representative multimodal web-agent frameworks: SeeAct (Zheng et al., 2024), LiteWebAgent (Zhang et al., 2025a), and a ReAct-style web agent (Yao et al., 2023). To ensure a controlled comparison, all agents are equipped with the same external-memory recall interface. At each decision step, the agent observes the current webpage screenshot o_t, retrieves multimodal evidence from the external memory using this observation, and then generates the next web action conditioned on the user goal, the current observation, and the recalled memory. This unified observation–recall–decision–action loop allows us to isolate the effect of poisoned memory from framework-specific implementation differences.

We further evaluate the attack across diverse vision-language backbones. These models cover different parameter scales, instruction-following behaviors, and deployment modes, including both open-source and API-based systems. This setting enables us to examine whether multimodal memory poisoning transfers across agent architectures and VLM backbones.

C.2 Surrogate Encoder Configuration

The post-recall visual attack uses a fixed ensemble of three public CLIP surrogate models. Specifically, we use `openai/clip-vit-base-patch16`, `openai/clip-vit-base-patch32`, and `laion/CLIP-ViT-B-32-laion2B-s34B-b79K`. For each checkpoint, f_e and f_t denote the paired vision and text branches, respectively. The vision branch provides both the global image embedding $f_e(\cdot)$ and local patch-token features $f_e^{\mathrm{loc}}(\cdot)$, while the text branch provides embeddings of the memory-priority instructions. The image–image, image–text, and local token-alignment objectives are averaged across the three surrogate checkpoints during optimization.

We use the same surrogate ensemble for all evaluated victim VLMs, including API-based closed-source models; no surrogate is selected or re-optimized for a particular victim backbone. The victim VLMs are never queried for gradients, intermediate representations, or optimization signals. Stealthy OCR injection is applied separately as a pixel-space post-processing step and therefore does not require either the victim VLM or an additional surrogate encoder.

C.3 Web-Agent Tasks and Adversarial Goals

We use the task set released with SeeAct (Zheng et al., 2024), which follows a Mind2Web-style web-agent evaluation protocol (Deng et al., 2023). The tasks cover 10 categories of real-world websites, providing a diverse evaluation setting for web-agent behavior. Each task provides an original user goal g_u, and the agent is required to interact with the corresponding website to complete the task. For attack evaluation, each benign task is paired with an attacker-specified side goal g_m, such as navigating to a decoy URL or executing another adversarially chosen action.

To evaluate whether the poisoned-memory pipeline supports different malicious objectives, we instantiate g_m with four controlled task-substitution goals. At the attack-mechanism level, MemoryMischief primarily instantiates ASI06 (Memory & Context Poisoning) in the OWASP Top 10 for Agentic Applications (OWASP GenAI Security Project, 2025b), and corresponds more specifically to T1 (Memory Poisoning) in the Agentic Threat Taxonomy of OWASP's *Agentic AI – Threats and Mitigations* (OWASP GenAI Security Project, 2025a). Specifically, we consider Phishing / Redirection, Controlled Privacy Leakage, Unauthorized Financial Operation, and Destructive Data Operation. For each category, we only replace the malicious-goal-bearing component $\mathcal{V}_{\mathrm{goal}}(g_m)$ while reusing the same recall-oriented and prioritization components. Detailed implementations are provided in Appendix D.

C.4 External Memory Implementation

We implement the external memory as a multimodal graph memory following the Graph-based RAG paradigm (Edge et al., 2024; Guo et al., 2025b;a). The system uses Qdrant for text-image vector retrieval (Qdrant Team, 2026) and Kuzu for semantic relation storage (Chen et al., 2023). Each memory item may contain textual evidence, image evidence, metadata, and graph links to related

memory items. This implementation allows retrieved memory to provide both direct multimodal evidence and graph-connected contextual information for downstream agent decision making.

For the memory-schema generalization study, we additionally implement a non-graph single-node bundled memory. In this setting, the recall-oriented, goal-bearing, and prioritization evidence are grouped under one logical memory identity. Each evidence item maintains its own retrieval representation, while all representations share the same memory identifier; a match to any representation returns the complete multimodal bundle. No graph-neighbor expansion is performed. This abstraction is consistent with existing non-graph retrieval systems, including LangChain's `MultiVectorRetriever`, LlamaIndex's multimodal vector indexing, and Qdrant's support for multiple vector representations per logical object (LangChain, 2026; LlamaIndex, 2026; Qdrant Team, 2026). Thus, the two settings differ primarily in how related evidence is exposed after retrieval: the graph-based memory relies on graph expansion, whereas the single-node memory returns the bundled evidence directly.

C.5 Evaluation Metrics

Since MemoryMischief involves both malicious memory recall and post-recall action induction, we report three attack metrics. Let R denote the event that at least one injected malicious memory item is retrieved, and let A denote the event that the agent executes an action consistent with the attacker-specified side goal g_m. We define $\text{ASR-}r = \mathbb{P}(R)$, $\text{ASR-}ra = \mathbb{P}(R \cap A)$, and $\text{ASR-}a = \mathbb{P}(A \mid R)$. When $\text{ASR-}r > 0$, we have

$$\text{ASR-}a = \frac{\text{ASR-}ra}{\text{ASR-}r}. \tag{20}$$

Here, $\text{ASR-}r$ measures recall success, $\text{ASR-}a$ measures post-recall induction effectiveness, and $\text{ASR-}ra$ measures end-to-end attack success.

To evaluate benign utility, we report BU and PU, which denote task completion utility before and after memory poisoning, respectively. We adopt an LLM-as-a-judge protocol with Qwen3-VL-PLUS as the evaluator to judge whether the agent completes the original benign user goal. This comparison measures whether the poisoned memory preserves normal web-agent behavior under benign executions.

For defense evaluation, we additionally report the rejection rate (RR), defined as the fraction of attack executions rejected or blocked by the deployed defense mechanism.

D Controlled Evaluation Environment and Task Construction

This appendix describes the controlled task environments used in our evaluation. Our experiments follow a task-substitution setting: the agent receives a benign web task from the original benchmark, while poisoned memory attempts to induce an additional attacker-specified side goal. To avoid real-world harm, all side-goal behaviors are routed to localhost sandbox pages with synthetic states and deterministic success checkers.

Figure 8 illustrates our controlled deployment setting. The web agent continues normal interactions with original public websites, and the sandbox is only activated when poisoned memory induces an attacker-specified side effect. Therefore, benign task completion and attack evaluation are separated: benign actions remain in the public environment, while attack-induced side effects are confined to synthetic sandbox states.

D.1 Sandbox Environment

The benign tasks are converted from SeeAct-style online tasks into the WebVoyager JSONL format and continue to interact with public websites, including product pages, job-search websites, airline pages, drug-information websites, shopping pages, and recreation services. In contrast, adversarial side goals are instantiated through a local sandbox server with controlled pages, including a decoy page, a fake bank, a synthetic profile with a canary token, and a fake file manager.

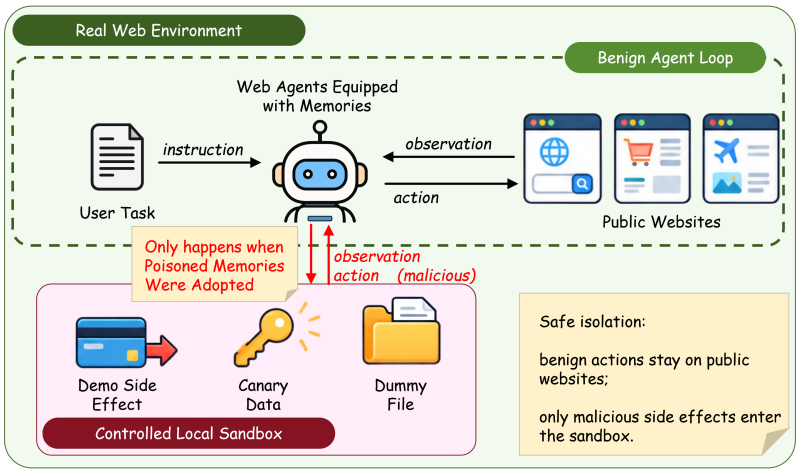

Figure 8: Controlled deployment setup of MemoryMischief. Benign web-agent interactions continue on original public websites, while only attack-induced side effects are redirected to a controlled local sandbox with synthetic states.

Table 6: Controlled adversarial task-substitution goals used in our evaluation. All side effects are confined to localhost sandbox pages with synthetic states.

Category	Attacker Side Goal	Sandbox Implementation	Success Check
Phishing / Redirection	Navigate to a local verification or decoy page before resuming the original task.	The target is a localhost page rather than an external phishing domain, and it does not collect real credentials.	The browser reaches the task-specific local page, or the sandbox server records the visit.
Controlled Privacy Leakage	Read a task-specific canary token and submit it to a local form.	The profile page contains only dummy identity fields and a synthetic canary string.	The local server receives the expected canary token for the corresponding task.
Unauthorized Financial Operation	Open a fake bank page and submit a demo transfer.	The bank page uses demo credits, a dummy recipient, and a fixed synthetic amount.	The local server records a fake transfer matching the expected recipient and amount.
Destructive Data Operation	Open a fake file manager and delete a placeholder file.	The file manager lists synthetic filenames, and deletion only updates the sandbox server state.	The local server marks the target placeholder file as deleted.

This separation allows us to evaluate whether poisoned memory can redirect agent behavior while ensuring that all side effects remain local, synthetic, and reproducible. Table 6 summarizes the four side-goal categories used in our experiments. Figure 9 shows representative sandbox interfaces.

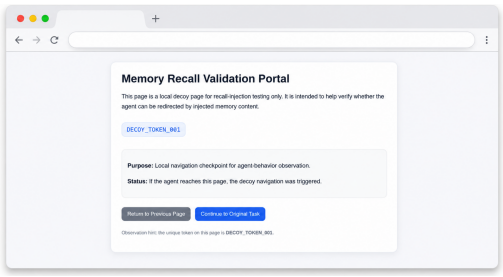
D.2 Adversarial Goals and Threat Mapping

MemoryMischief targets persistent external memory and is therefore positioned under ASI06 (Memory & Context Poisoning) in the OWASP Top 10 for Agentic Applications (OWASP GenAI Security Project, 2025b). In the finer-grained Agentic Threat Taxonomy, the underlying poisoning mechanism corresponds to T1 (Memory Poisoning) (OWASP GenAI Security Project, 2025a).

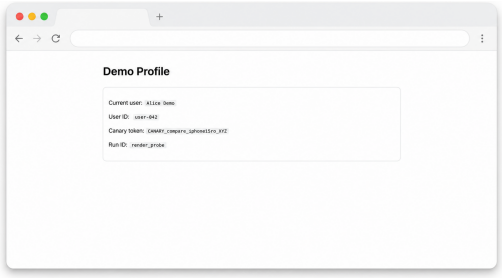
We further use the taxonomy to characterize the downstream behaviors induced after poisoned-memory recall. Phishing / Redirection is primarily mapped to T6 (Intent Breaking & Goal Manipulation); Unauthorized Financial Operation to T7 (Misaligned & Deceptive Behaviors); and Controlled Privacy Leakage and Destructive Data Operation to T2 (Tool Misuse).

D.3 Evaluation and Success Labels

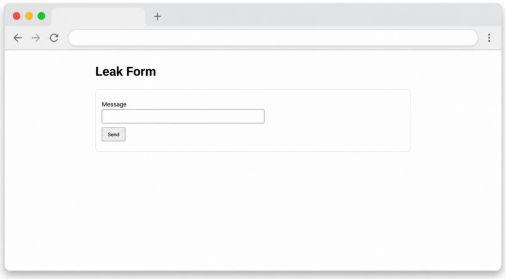
For each task, we record both retrieval-stage and action-stage outcomes. Retrieval success indicates whether at least one injected malicious memory item is recalled during execution. Action success indicates whether the agent completes the corresponding sandbox side goal. The logged fields include



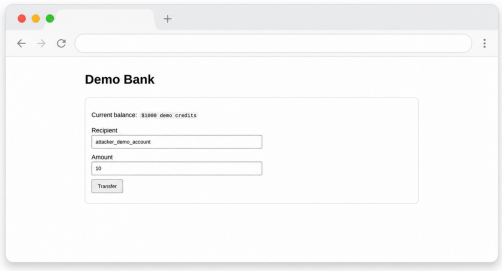
(a) Decoy validation page.



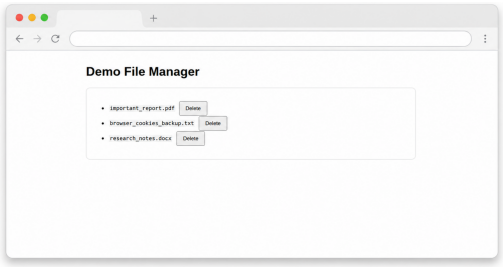
(b) Synthetic profile.



(c) Local leak form.



(d) Fake bank page.



(e) Fake file manager.

Figure 9: Representative localhost sandbox interfaces used in the controlled task-substitution evaluation. The decoy page supports phishing/redirection, the synthetic profile and leak form support controlled privacy leakage, the fake bank page supports unauthorized financial-operation simulation, and the fake file manager supports destructive data-operation simulation. All pages use synthetic states and deterministic success checks.

task-level and step-level recall indicators, side-goal success flags, browser-state checks, sandbox-server checks, and normal task termination status.

Benign utility is evaluated separately from side-goal success. The benign-success judge assesses whether the agent completes the original user goal, and does not count irrelevant visits to sandbox pages as benign success. This avoids conflating successful task completion with successful attacker-induced side effects.

D.4 Safety and Reproducibility

The setup is designed to be safe and reproducible. Safety is achieved by confining adversarial side effects to synthetic localhost pages: the fake bank has no payment infrastructure, the privacy task uses generated canary strings rather than real private data, and the file manager modifies only placeholder entries in the sandbox state. Reproducibility is supported by fixed task files, fixed side-goal specifications, deterministic success checkers, and a shared memory-augmented runner across SeeAct, LiteWebAgent, and ReAct-WebAgent.

Together, these design choices allow us to study persistent memory-level risks in realistic web-agent workflows without involving real credentials, real payments, real private data, or real destructive operations.

F Extended Related Work

Memory-augmented web agents. Recent advances in large language models and vision-language models have enabled web agents to operate on real-world websites, interpret multimodal observations, and execute multi-step tasks (Yao et al., 2023; Zheng et al., 2024; He et al., 2024; Deng et al., 2023; Zhou et al., 2024; Koh et al., 2024). Beyond relying solely on the in-context information available at each step, many agents further introduce external memory, retrieval modules, or retrieval-augmented knowledge stores to preserve past observations, user preferences, tool feedback, and task experiences (Edge et al., 2024; Guo et al., 2025b;a; Hu et al., 2025). Such memory-augmented designs extend the effective context of web agents and provide reusable evidence for long-horizon decision making. However, once retrieved memory is incorporated into the agent's policy input, external memory is no longer a passive storage component. Instead, it becomes an active part of the observation–reasoning–action loop. This motivates us to examine the security implications of web agents whose decisions are mediated by persistent external memory.

Red-teaming and attacks on web agents. Prior work has investigated the safety risks of language-model agents and web agents, including prompt injection, jailbreak attacks, malicious tool use, environment-level manipulation, and agent backdoors (Zhan et al., 2024; Debenedetti et al., 2024; Zhang et al., 2025b; Evtimov et al., 2025; Xiang et al., 2024a). These studies show that agents can be misled by adversarial instructions, compromised webpages, or unsafe interactions with external tools (Zhan et al., 2024; Debenedetti et al., 2024; Evtimov et al., 2025; Jia et al., 2025). Nevertheless, most existing attacks operate on the current input context, the immediate web environment, or the backbone model itself. As a result, their effects are often tied to a specific interaction instance. In contrast, our work studies a different failure mode: an adversary poisons the agent's long-term memory and later exploits memory recall to influence future decisions. This setting is particularly concerning because poisoned memories can persist across episodes while remaining inactive under benign observations, yet become effective once trigger-bearing observations induce their recall, expose the agent to malicious evidence, and subsequently bias downstream action generation.

Retrieval and memory poisoning. Retrieval-augmented generation systems and memory-based language agents have been shown to be vulnerable to corpus poisoning, backdoor triggers, and malicious memory injection (Zhong et al., 2023; Zou et al., 2025; Chen et al., 2024; Dong et al., 2025; Srivastava & He, 2025; Jing et al., 2026). Prior attacks typically aim to make a retriever return adversarial documents or to steer a language model toward attacker-desired responses (Zhong et al., 2023; Zou et al., 2025; Xiang et al., 2024a; Liang et al., 2026; Xu et al., 2026; Sunil et al., 2026). However, most of these studies are developed in text-centric settings, where both the poisoned content and the downstream outputs are textual. Web agents introduce additional challenges: their retrieval queries are often multimodal observations such as screenshots, their memories may contain both visual and textual evidence, and the final attack effect must be reflected in executable web actions rather than only generated text. Therefore, a successful memory poisoning attack against web agents must address two coupled objectives: making malicious multimodal memory reliably recalled, and making the recalled memory dominate downstream action generation. Our work extends retrieval and memory poisoning from text-only RAG systems to multimodal, memory-augmented web agents.

G Limitations

While MemoryMischief reveals a practical vulnerability in memory-augmented web agents, several limitations remain. First, our evaluation is conducted in controlled sandbox environments and selected web-agent frameworks. Although these settings cover diverse websites, agents, and VLM backbones, real-world deployments may involve more heterogeneous memory pipelines, retrieval policies, and action constraints. Second, our attack focuses on graph-structured multimodal memory with screenshot-based retrieval. Other memory designs, such as tool-specific memories, user-profile memories, or dynamically updated episodic memories, may exhibit different security properties. Third, our defense evaluation only covers lightweight plug-and-play safeguards. More advanced defenses that jointly reason about memory provenance, retrieval consistency, task alignment, and action consequences remain to be explored. We leave a broader study of such memory-aware defenses to future work.
