WEBDEVHORIZON: EVALUATING CODING AGENTS ON COMPLETE WEB FEATURE DELIVERY

Anonymous authors
Paper under double-blind review

ABSTRACT

Driven by rapid advances in large language models, autonomous coding agents are increasingly being applied to full-stack Web development. Existing benchmarks, however, typically evaluate either the resolution of isolated repository-level issues or the greenfield development of Web applications from scratch. In practice, developers regularly implement user-facing features within established Web codebases. Delivering such features is inherently a long-horizon, cross-layer endeavor: an agent must understand and modify frontend interfaces, backend logic, and often database schemas, while keeping states synchronized across these layers through iterative test and runtime feedback. Yet, it remains uncertain how reliably autonomous agents can complete such full-stack feature implementation tasks. In this paper, we introduce WebDevHorizon, a benchmark for long-horizon, full-stack Web feature delivery. It comprises 114 tasks obtained from 52 releases across 24 public repositories. Each task corresponds to a product feature shipped by the repository maintainers, with its behavioral requirements reconstructed from the project's development history. To evaluate feature-level behavioral completeness, WebDevHorizon maps these requirements to executable checks of component behavior, API contracts, persistent state, and browser workflows as needed. The environments and test suites are human-verified, and a task is resolved only when all target and regression checks pass. Evaluating eight frontier LLMs with `mini-swe-agent` highlights the difficulty of long-horizon delivery: across trajectories averaging 56–161 agent steps per task, models resolve 40.35%–63.16% of tasks, led jointly by Opus-5 and GPT-5.6-Sol.

1 INTRODUCTION

Driven by rapid advances in large language models, autonomous coding agents are increasingly applied to full-stack Web development (Anthropic, 2025). In real-world development, a central demand is delivering complete, user-facing features within established Web codebases, where over half of surveyed engineers report full-stack responsibilities (Huang et al., 2025).

Full-stack feature delivery in web applications introduces distinct challenges for coding agents. First, delivery is a long-horizon task requiring coordinated changes across the frontend, backend, and, where necessary, persistent application state or services. These dependencies may also cross programming-language boundaries. Second, verifying delivery requires checking the requested behavior and potential regressions across the affected layers, using component tests, HTTP/API checks, database assertions, and browser workflows as appropriate. Yet existing benchmarks do not systematically target complete, cross-layer feature delivery in established codebases. Repository-level benchmarks cover bug fixing and feature implementation, but are not designed specifically to evaluate coordinated frontend and backend feature development across diverse existing Web applications (Jimenez et al., 2024; Yang et al., 2025; Miserendino et al., 2025; Zhou et al., 2026; Jiang et al., 2026; Chen et al., 2026). Meanwhile, benchmarks that do target full-stack web applications focus on greenfield generation from scratch (Lu et al., 2026; Tran et al., 2026), omitting the challenge of navigating, extending, and preserving established production systems (see Table 1).

To address these evaluation gaps, an evaluation framework for full-stack web feature delivery should satisfy three design principles:

Reviewers: please read the Reviewer Guidelines (iclr.cc/Conferences/2027/ReviewerGuidelines) and the AI Policy for Reviewers (iclr.cc/Conferences/2027/AIPolicyForReviewers). If you used AI to expand, edit, or polish your review, please provide the input text to the LLM. Better still, consider skipping the LLM and submitting your original text: we, and the authors, are much more interested in your unedited thoughts than in what an LLM has to say. AI-assisted or not, you are putting your name and reputation behind your review: LLM-generated falsehoods, hallucinations or misrepresentations are subject to disciplinary action, which may include desk-rejecting all papers you have authored.

Table 1: Comparison of task units and execution evidence across coding benchmarks.

Benchmark	Task unit	Lang.	Evaluation evidence		
			Code tests	Live API / state	Browser checks
SWE-bench (Jimenez et al., 2024)	Repository issue	Py	●	–	–
SWE-bench Multimodal (Yang et al., 2025)	Visual repository issue	JS/TS	●	–	○
SWE-Lancer (IC) (Miserendino et al., 2025)	Freelance engineering job	JS/TS	–	–	●
FeatureBench (Zhou et al., 2026)	Test-isolated feature	Py	●	–	–
Doc2Feat-Bench (Jiang et al., 2026)	Documented feature	Py	●	–	–
FeatBench (Chen et al., 2026)	Release-linked feature	Py	●	–	–

FullStack-Bench (Lu et al., 2026)	New Web application	JS/TS, Py	–	●	●
Vibe Code Bench (Tran et al., 2026)	New Web application	JS/TS	–	○	●
WEBDEVHORIZON (ours)	**Shipped full-stack feature**	**Multi.**	●	●	●

Benchmark-level evidence: ● explicit; ○ limited/indirect; – not separately specified. *Multi.*: multiple languages.

1. **Shipped product feature as task unit.** Each task should represent one complete feature in an existing Web application, with coordinated frontend and backend changes and, where needed, database changes. Where required by the feature, these changes may span multiple programming languages, requiring the agent to coordinate behavior and interfaces across language boundaries.
2. **Natural product request as task interface.** The agent should receive a natural-language request stating the desired capability from a user or stakeholder perspective. The request may specify required public interface names and behavior; the agent must locate the affected code and state and decide how to implement the change.
3. **Feature-dependent, multi-surface evidence.** Evaluation must verify the feature's target behavior and guard against regressions across relevant observable surfaces, including component logic, API contracts, persistent database state, and browser-visible workflows.

To operationalize these principles, we introduce WEBDEVHORIZON, comprising 114 full-stack feature tasks reconstructed from 52 releases across 24 public Web repositories. The selected codebases span diverse frontend frameworks (e.g., React, Vue), backend runtimes (e.g., Node.js, Python), and database engines (e.g., PostgreSQL, SQLite). Each task centers on a user-facing capability originally shipped by maintainers in a production release.

We construct WEBDEVHORIZON in the following stages: First, rather than treating individual pull requests (PRs) as isolated tasks, we reconstruct feature boundaries from release notes and linked merged PRs. Release notes supply product-level descriptions of maintainer-shipped changes (Yu, 2009; Bi et al., 2022), while linked merged PR records provide implementation evidence. We decompose this evidence into behavioral requirements, grouping related PRs into one task when they support the same product capability. Second, a human expert and a language model collaboratively draft each task prompt from a stakeholder perspective, specifying intended behavior and constraints without leaking internal file paths, implementation hints, or prescriptive test checklists. Third, we assess repository-native tests against the behavioral requirements and supplement incomplete coverage with targeted checks across component logic, HTTP/API contracts, persistent database state, and real-browser workflows as needed. Finally, three experts review each candidate task to ensure that it reflects the shipped feature, clearly specifies the expected behavior and constraints, and includes executable checks covering the stated requirements. We revise each task until all three agree that the identified issues have been addressed. Admission to WEBDEVHORIZON further requires differential execution: all target checks must fail on the initial repository state for the intended reasons and pass on the reference implementation, while all regression checks must pass in both states. A task is considered resolved only when the agent's implementation passes every declared target and regression check.

Evaluating eight frontier LLMs (Opus-5 (Anthropic, 2026), GPT-5.6-Sol (OpenAI, 2026), DeepSeek-V4-Pro (DeepSeek, 2026a), DeepSeek-V4-Flash (DeepSeek, 2026b), Kimi-K3 (Moonshot AI, 2026),

Qwen3.8-Max (Qwen Team, 2026), GLM-5.2 (Zhipu AI, 2026), and Hy3 (Tencent Hunyuan Team, 2026)) using `mini-swe-agent` (SWE-agent Team, 2025) at maximum reasoning effort yields resolution rates between 40.35% and 63.16%. Opus-5 and GPT-5.6-Sol each resolve 72 of 114 tasks (63.16%); both leave more than one-third of the tasks unresolved. Across all models, performance drops consistently on tasks requiring larger reference implementations or database schema migrations. We further find substantial limitations in models' use and generation of tests: across models, only 31.0%–67.5% of tasks with a passing last observed local test run are ultimately resolved.

2 Related Work

Repository-level software engineering benchmarks evaluate coding agents through executable tests in existing repositories. While early efforts focus on issue resolution and bug fixing (Jimenez et al., 2024; Vergopoulos et al., 2025; Yang et al., 2025; Miserendino et al., 2025), recent benchmarks increasingly target feature implementation. Much of this work centers on Python repositories: FEA-Bench validates feature-adding pull requests with unit tests (Li et al., 2025); Doc2Feat-Bench pairs documentation changes with feature pull requests and repository tests (Jiang et al., 2026); FeatBench synthesizes natural-language requirements from reference patches (Chen et al., 2026); and FeatureBench derives callable interfaces by tracing test dependency graphs rather than using pull requests directly (Zhou et al., 2026). Across languages, ABC-Bench masks endpoint logic in existing backend repositories and evaluates deployed services via API tests (Yang et al., 2026). At a broader task granularity, SWE-EVO evaluates entire release deltas that can combine features, bug fixes, and maintenance (Thai et al., 2025). WebDevHorizon differs in its task formulation: rather than evaluating isolated pull requests or release deltas, WebDevHorizon focuses on complete full-stack feature delivery in existing Web applications, requiring coordinated frontend and backend changes and, where necessary, changes to persistent state or services.

Another line of research investigates end-to-end Web generation. Benchmarks such as FullStack-Bench and Vibe Code Bench evaluate synthesizing complete Web applications from scratch (Lu et al., 2026; Tran et al., 2026), while WebArena examines autonomous agents operating existing websites (Zhou et al., 2024). Because unconstrained greenfield generation produces arbitrary architectures, these benchmarks frequently rely on autonomous agents or LLM judges, which may introduce evaluation noise. Moreover, building applications from scratch bypasses the core realities of real-world software engineering: navigating established codebases, adhering to existing architectures, and safeguarding against regressions. In contrast, WebDevHorizon anchors tasks in mature Web repositories with fixed interface contracts, evaluating feature delivery through deterministic, multi-surface executable tests without relying on LLM judges.

3 WebDevHorizon

WebDevHorizon comprises 114 tasks from 52 releases across 24 repositories. Figure 1 summarizes the benchmark construction pipeline and evaluation interface.

3.1 Task Definition and Evaluation Contract

Each task pairs an existing full-stack Web repository at a fixed base commit with a natural-language request for a complete product feature. Written from a stakeholder's perspective, the request specifies the desired capability and necessary public interface constraints without disclosing internal file paths or implementation guidance. The agent must inspect the codebase and produce a repository patch, while the reference implementation and task evaluator remain strictly hidden during execution.

Following the evaluation convention of repository benchmarks (Jimenez et al., 2024), each task specifies fail-to-pass (F2P) target checks that verify the requested capability and pass-to-pass (P2P) regression checks that safeguard existing functionality. F2P checks fail on the base commit and pass on the reference implementation, whereas P2P checks pass across both states. An agent resolves a task if and only if all declared F2P and P2P checks pass on the modified repository within its containerized environment.

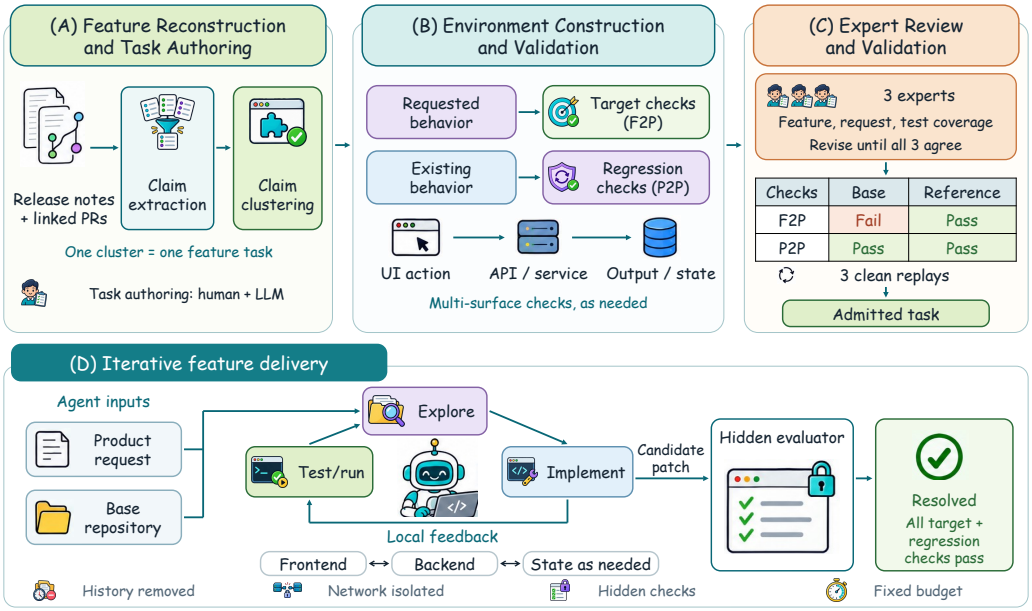

Figure 1: WEBDEVHORIZON construction and evaluation protocol.

3.2 SOURCE APPLICATIONS AND RELEASES

We collect tasks from actively maintained full-stack Web repositories on GitHub across five application domains: business and operations, collaboration and content management, personal applications, media services, and education. To ensure code quality and community relevance, we require each repository to have at least 500 stars, prioritizing those with higher adoption (Table 5).

To capture recent product-development needs and reduce potential contamination, we start from release notes published in 2026 and inspect their linked, merged PRs. Because release notes summarize customer-facing capabilities shipped by maintainers, they provide an authentic basis for defining product features (Yu, 2009; Bi et al., 2022) (Figure 1(A)). The source pool contains 223 release notes. Among their linked PRs, we exclude those limited to documentation updates, dependency updates, or maintenance unrelated to product functionality, and retain those that modify implementation code for subsequent feature reconstruction.

3.3 FEATURE RECONSTRUCTION AND TASK AUTHORING

PR boundaries do not necessarily coincide with product requirements: a single PR can mix a user-facing feature with refactoring or other maintenance (di Biase et al., 2019). We therefore reconstruct tasks around observable product behavior rather than treating each PR as a task. For each release entry and linked PRs, we extract user-observable requirements from the release notes, PR descriptions, and code diffs using the claim-extraction prompt in Appendix E. The prompt cross-references claimed behavior with the underlying code diffs, discarding entries that lack concrete implementation evidence. Each resulting claim specifies a distinct operational outcome, yielding 4,514 candidate claims.

We then cluster these claims into feature candidates using the feature-grouping prompt in Appendix E (Figure 1(A)). This isolates self-contained product capabilities, separating unrelated operations even when co-occurring in the same PR. The resulting boundary anchors both downstream artifacts: its constituent claims determine the functional requirements specified in the task request and define the observable behaviors verified by the target checks.

To select full-stack tasks, we retain candidates whose reference patches span both frontend and backend modules, and identify database migrations where present, based on the architectural path heuristics in Appendix A.2. We exclude candidates that share PRs with other features to ensure task independence. Inspired by prior work that applies patch-size limits during task collection (Badertdinov et al., 2025; Jain et al., 2025), we cap reference patches at 80 files and 3,000 modified lines to bound

implementation scope. Finally, assisted by frontier LLMs[1], we review each candidate, verifying that the feature forms a coherent capability with complete source evidence.

To mirror realistic development, we draft product requests from a user or stakeholder perspective with frontier LLM assistance. Each request specifies only the intended capability and required public interface contracts, without providing internal file paths, code locations, or prescriptive checklists. We audit each draft against its associated claims to verify behavioral accuracy and prevent information leakage (Appendix E), yielding 176 reviewed requests. Finally, we anchor each task to its base commit and assemble the maintainers' merged changes into a reference patch for subsequent validation.

3.4 Environment Construction and Validation

For each candidate, we build a containerized environment at its base commit through LLM-assisted configuration and manual inspection, resolving runtime or environment issues by repairing dependency manifests, build scripts, and service definitions. Where tasks require a live application, we connect frontend interfaces to backend services and initialize necessary databases and fixture data. We verify that all dependencies install cleanly, background services start reliably, and the test harness executes without infrastructure errors, discarding candidates with unresolved build, startup, or test-execution failures.

In each environment, we construct a task-specific evaluator from the feature's claims (Figure 1(B)). Passing repository tests does not necessarily establish complete feature delivery (Beller et al., 2019); for instance, a study of GitHub Java projects reports a median branch coverage of approximately 43% among the 310 projects with coverage measurements (Khatami & Zaidman, 2024). We reuse applicable repository tests and use frontier LLMs to draft supplemental checks for claimed behaviors those tests do not exercise. Guided by the claims and existing test framework, the models generate checks at the relevant execution surfaces: component tests for frontend interactions, HTTP/API checks for service behavior, database assertions for persistent effects, and Playwright browser workflows for operations spanning layers, as needed. Across WebDevHorizon, all 114 task packages include dedicated supplemental test files. Any missing execution dependencies identified during test development trigger further environment repairs. Appendix A.4 illustrates end-to-end feature delivery through a selective envelope duplication task from Documenso.

Three experts then review each candidate task against its source evidence, product request, and evaluator. They check that the claims match the shipped feature, the request clearly states the expected behavior and constraints, and the checks exercise the claimed outcomes across the relevant architectural layers. We revise each task until all three agree that the identified issues have been addressed (see Appendix A.6 for details).

We validate each candidate through differential execution gating between the base commit and the reference implementation (Figure 1(C)). This construction gate requires all F2P target checks to fail on the base commit specifically due to the missing capability and pass on the reference implementation, with all P2P regression checks passing across both states. Following repeated-execution protocols from recent executable coding benchmarks (Huang et al., 2026; Wang et al., 2025; Deng et al., 2026), we replay each task three times in clean, identically pinned environments. Candidates are admitted only if all checks yield deterministic outcomes across all replays; any flakiness or platform error triggers repair or exclusion. This yields 114 validated tasks, each pairing a product request and base commit with an isolated container and a hidden multi-surface evaluator.

3.5 Dataset Characteristics

WebDevHorizon comprises 114 full-stack feature tasks from 52 releases published in 2026[2] across 24 public Web repositories, spanning five domains: business and operations, collaboration and content management, personal applications, media services, and education. Table 2 summarizes task and evaluator sizes. All 114 reference implementations modify frontend and backend code; 11 (9.6%) also modify database schemas or migrations (Appendix A.2). Detailed distributions appear in Appendix A.7.

[1] We use Opus-5 for candidate review, request drafting, and supplemental-check generation.

[2] January 4–July 29, 2026.

Application and requirement diversity. The benchmark spans diverse real-world software domains and feature intents (Figure 2(a–b)). The largest application domains are business and operations (40 tasks) and collaboration and content management (34 tasks). Across seven primary product intent categories, the most frequent are identity and access and interface and visualization.

Behavioral claims and test coverage. In total, the benchmark comprises 254 audited behavioral claims, with a median of 2 claims per task (ranging from 1 to 8). Each claim defines an observable invariant or workflow, which often consolidates multiple input variations or access conditions under a unified requirement. To examine whether our evaluation extends beyond simple happy-path scenarios, we classify task checks into concrete behavioral categories. These categories cover UI behavior, error handling and boundary conditions, API contracts, and state mutations. Across the benchmark, 91 tasks verify UI rendering and interaction, 85 inspect error handling, defaults, and boundary conditions, and 81 evaluate API contracts and data serialization (Figure 2(c)). Individual tasks can belong to multiple categories, reflecting the range of behaviors checked within a single feature (see Appendix A.7 for the annotation rubrics).

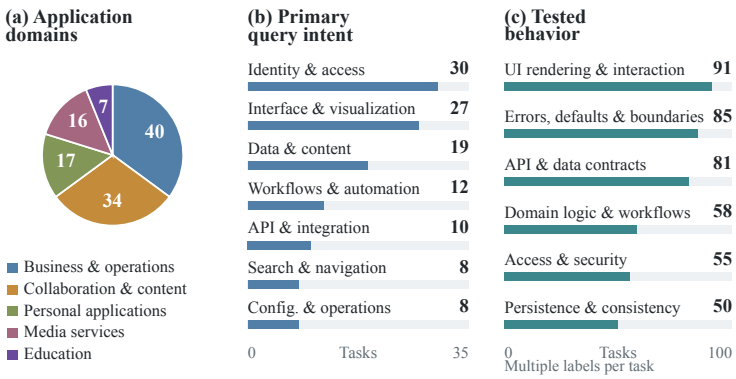

Table 2: Median task attributes.

		Median
Query	Length (words)	81.5
Codebase	# Lines (non-test)	429K
	# Files (non-test)	2,201.5
Gold patch	# Lines edited	139
	# Files edited	7
	# Functions edited	10
Tests	# Fail to Pass	3
	# Pass to Pass	1

Figure 2: All 114 tasks by **(a)** application domain, **(b)** primary query intent, and **(c)** tested behavior. Panels (a)–(b) assign one label per task; panel (c) allows multiple labels per task based on declared F2P target and P2P regression checks.

4 Evaluation Design

Models. We evaluate eight frontier LLMs, covering both proprietary and open-source models: Opus-5 (Anthropic, 2026), GPT-5.6-Sol (OpenAI, 2026), Kimi-K3 (Moonshot AI, 2026), Qwen3.8-Max (Qwen Team, 2026), DeepSeek-V4-Pro (DeepSeek, 2026a), DeepSeek-V4-Flash (`DeepSeek-V4-Flash-0731`) (DeepSeek, 2026b), GLM-5.2 (Zhipu AI, 2026), and Hy3 (Tencent Hunyuan Team, 2026). We configure each model at its highest supported reasoning effort to evaluate it under a high-reasoning-budget setting.

Agent. We use mini-swe-agent as the fixed, model-agnostic scaffold for the headline comparison, giving every model the same `bash` interface and shared prompt so that scores primarily reflect model capability rather than harness design (SWE-agent Team, 2025; Huang et al., 2026). To evaluate the influence of harness engineering, we additionally test GPT-5.6-Sol with Codex and Opus-5 with Claude Code in their native environments, quantifying performance differences between vendor-specialized agent products and a standardized scaffold.

Evaluation Metrics. The primary metric is task-level resolved rate: the fraction of tasks for which every F2P target check and P2P regression check passes. We additionally report mean agent steps, input and output tokens, and estimated inference cost.

Evaluation Sets and Isolation. All evaluations run across the identical set of 114 tasks (detailed execution protocols in Appendix B.1). To prevent information leakage, the agent receives strictly the natural-language request and a codebase snapshot at the base commit stripped of all Git commit history, ensuring reference patches, release notes, and historical commits cannot be retrieved.

Each attempt launches a fresh Docker container from the pinned task image with a clean checkout of the base commit and reset database fixtures. The container operates with no outbound internet access; necessary application services communicate exclusively over an isolated Docker network. To accommodate complex feature delivery, we allocate an interaction budget of up to 5,400 seconds for the agent, providing sufficient time to explore the codebase, implement multi-file changes, and iterate against local tests (Huang et al., 2026). Afterward, an independent evaluator receives up to 1,800 seconds to execute the hidden F2P target and P2P regression checks.

5 Results and Analysis

5.1 Results

Table 3 reports the performance of eight coding models on WebDevHorizon using the mini-swe-agent scaffold. Following prior work (Deng et al., 2025; Zhang et al., 2025; Yang et al., 2025), we report Pass@1 as the resolved rate. To balance evaluation cost, we evaluate a controlled subset under Avg@3 (Appendix A.5) and observe results consistent with our primary findings.

We observe that current coding models still struggle to satisfy the complete feature specifications evaluated by the benchmark. Across the eight models, resolved rates range from 40.35% to 63.16%; GPT-5.6-Sol and Opus-5 achieve the highest resolved rate of 63.16% at maximum reasoning effort, leaving more than a third of the tasks unresolved.

Table 3: Performance and resource use under mini-swe-agent on WebDevHorizon.

Model (Reasoning Effort)	Resolved (%)	Avg. Agent Steps	Avg. Tokens (M)		Avg. Cost
			In	Out	
Opus-5 (max)	**63.16**	149.36	16.649	0.059	$84.71
GPT-5.6-Sol (max)	**63.16**	56.41	6.726	0.034	$4.00
DeepSeek-V4-Pro (max)	60.53	146.29	23.632	0.055	$0.29
Kimi-K3 (max)	60.53	128.04	10.281	0.047	$4.81
Qwen3.8-Max (xhigh)	58.77	135.31	12.604	0.057	CNY 153.29
DeepSeek-V4-Flash (max)	56.14	160.54	17.161	0.059	$0.11
GLM-5.2 (max)	46.49	133.42	9.177	0.030	CNY 19.81
Hy3 (high)	40.35	103.54	5.899	0.044	$0.41

The models reveal clear trade-offs across resolution performance, interaction efficiency, and inference cost. While GPT-5.6-Sol and Opus-5 achieve identical top resolution (63.16%), GPT-5.6-Sol operates with substantially higher efficiency: it requires under 41% of the agent steps (56.41 vs. 149.36) and token volume (6.76M vs. 16.71M), reducing mean per-task cost from $84.71 to $4.00. DeepSeek-V4-Pro delivers competitive performance, resolving 60.53% of tasks at an average cost of $0.29 per instance. Among USD configurations, DeepSeek-V4-Flash has the lowest mean cost ($0.11) but requires the most steps (160.54) while resolving 56.14%.

5.2 Analysis

To understand what impedes feature delivery, we analyze how task complexity, agent validation behavior, and execution scaffolds shape performance, concluding with a qualitative investigation of failure mechanisms (extraction protocols in Appendix B.1 and case evidence in Appendix B.3).

Task scale and database migrations sharply reduce resolution rates. Resolution rates for all eight models decline monotonically with implementation size (Figure 3), dropping from 70.0–93.3% on small features ($\leq$50 lines) to 25.9–51.9% on changes exceeding 150 lines. Task scale also alters model rankings: while Opus-5 leads on medium-sized changes of 51–150 lines (73.3%), GPT-5.6-Sol exhibits greater resilience on larger tasks exceeding 150 lines. Tasks that require database schema or migration changes alongside frontend and backend modifications (11 tasks) prove challenging across the board, with every model resolving only three to six instances.

Early cross-layer validation guides efficient full-stack delivery. Models that validate earlier and structure changes around explicit test contracts navigate long-horizon tasks more efficiently.

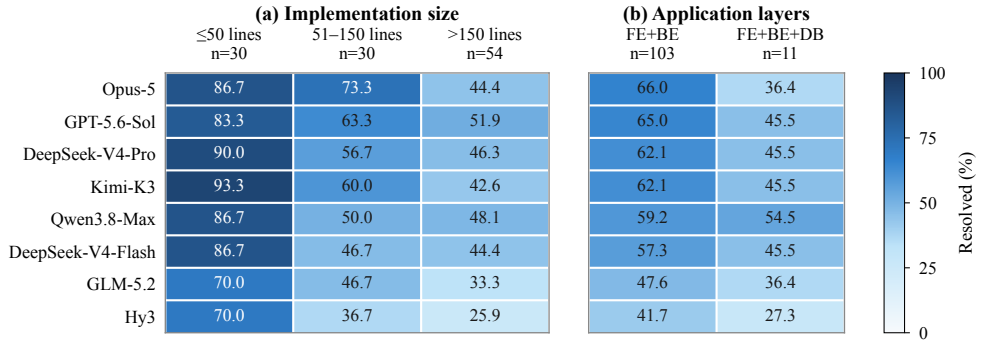

Figure 3: Resolved rates (%) by reference implementation size and application layers (FE: frontend; BE: backend; DB: database).

Figure 4 shows the distributions of shell-action counts and first-test positions, and Table 3 shows mean agent steps. Across models, recognizable test invocations occur in 64.9%–93.0% of trajectories, but the timing of validation diverges sharply: GPT-5.6-Sol initiates testing at a median of 36.8% into its action sequence, validating markedly earlier than GLM-5.2 and Hy3. This earlier verification correlates with more compact execution: GPT-5.6-Sol achieves the shortest median trajectory of 77.5 shell actions (49 agent steps), compared with 169.5 shell actions for DeepSeek-V4-Pro.

Case-level analysis reveals that this efficiency reflects a test-driven pattern coupling frontend and backend changes around shared behavioral contracts. In a representative Koel task linking API edit/delete permissions to frontend menu items, GPT-5.6-Sol first authors reproduction tests covering backend authorization and UI rendering, exposing missing functionality before touching production code, and then delivers both updates in concert. In contrast, DeepSeek-V4-Pro follows a sequential trial-and-error approach: it implements the backend first, pauses to diagnose failing regression checks (even testing whether failures persist with its patch reverted), and only then addresses the frontend. While both models ultimately resolve the task, GPT-5.6-Sol succeeds in 34 agent steps versus 65 for DeepSeek-V4-Pro (Appendix B.3).

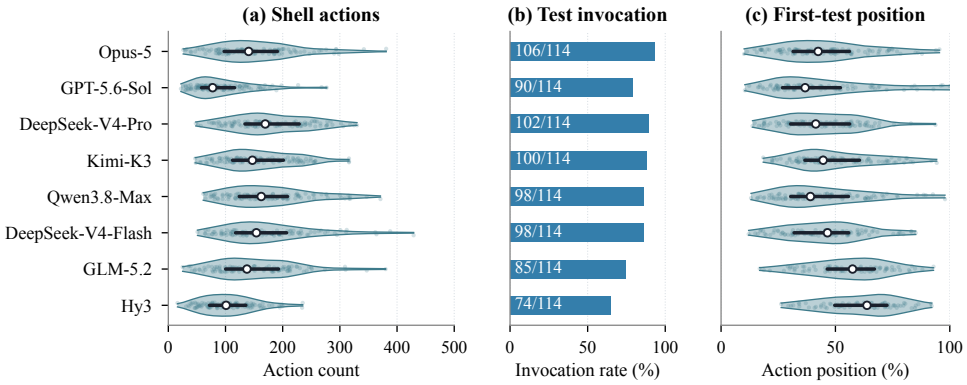

Figure 4: Agent interaction and validation. (a) Shell-action counts. (b) Histories with a recognized test invocation, labeled as count/114. (c) First-test action positions among histories in (b). White dots and dark segments mark medians and interquartile ranges; faint points show individual histories.

Models have room to improve their use and generation of tests. We examine whether passing local tests, either reused from the repository or generated by the agent, reliably predicts success under our hidden task-level evaluation. Figure 5(a,b) groups tasks by the last recognized local test result and reports the final resolved rate within each group. Local test success provides substantial false confidence: GPT-5.6-Sol observes passing final local tests in 77 of 114 tasks but resolves only 52 of them (67.5%), while Opus-5 observes 84 local passes yet resolves only 53 (63.1%). Across all eight models, resolution rates among locally passing trajectories range from just 31.0% to 67.5%.

Trajectory audits highlight two recurring mechanisms behind this validation gap (Appendix B.3). First, local tests commonly exhibit scope mismatches: models test isolated backend functions while

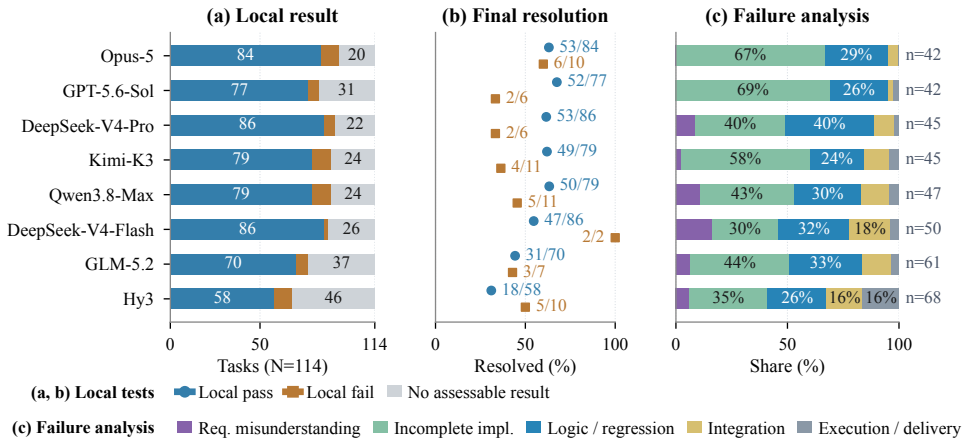

Figure 5: Local validation and failure categorization. **(a)** Final local test outcomes. **(b)** Resolution rates grouped by local test outcome (labeled as resolved/total). **(c)** Failure classification.

assuming upstream user workflows succeed, leaving end-to-end interactions unexercised. Second, models can author flawed test assertions that expect the same incorrect behavior implemented in their candidate code. Consequently, local test suites pass while leaving core feature requirements unverified or actively validating buggy behavior. These failure modes underscore two essential requirements for agent self-validation: generating checks that exercise full user workflows, and deriving assertions strictly from task specifications rather than implementation assumptions.

Scaffold design substantially influences feature delivery. To quantify the impact of the agent harness, we compare GPT-5.6-Sol and Opus-5 across the mini-swe-agent scaffold and their native harnesses (Codex and Claude Code). As reported in Table 4, both models achieve higher resolution under mini-swe-agent (63.16% each) than under their native harnesses (55.26% for Codex and 52.63% for Claude Code). This pattern aligns with recent benchmark findings (Huang et al., 2026). One plausible explanation is mini-swe-agent's structured prompt workflow that systematically instructs agents to localize code, reproduce defects, iterate on patches, and execute test suites (SWE-agent Team, 2025).

Table 4: Resolved rates (%) by harness.

Model	mini-swe-agent	Native
GPT-5.6-Sol	63.16	55.26
Opus-5	63.16	52.63

Incomplete implementation and incorrect logic dominate the identified failures. To diagnose why models fail, we retain source-assisted failure audits for the unresolved runs using DeepSeek-V4-Pro (procedure and taxonomy rubrics in Appendix B.2). By jointly analyzing the task request, agent patch, interaction trajectory, reference implementation and test patches, the judge classifies the primary failure mechanism for each audited attempt. As shown in Figure 5(c), incomplete implementation accounts for 187 failures (46.8%), and logic errors or regressions for 120 (30.0%). Together, these categories represent 76.8% of unresolved runs; the remaining failures involve cross-layer integration, requirement misunderstanding, and execution or delivery.

6 Conclusion

We present WebDevHorizon, a benchmark of 114 shipped features in existing Web repositories. Each task pairs a natural-language request reconstructed from release history with multi-surface checks across UI, API, and persistent state as required by the feature. Opus-5 and GPT-5.6-Sol achieve the highest resolved rate of 63.16%, leaving more than one-third of tasks unresolved. Passing local tests does not guarantee complete delivery, as incomplete implementations can still escape these checks. These findings highlight the need for agents to coordinate cross-layer changes and validate complete user workflows.

Reproducibility Statement

Section 3 describes task construction, expert review, and differential validation. Section 4 specifies the evaluated models, agent scaffolds, execution budgets, and isolation settings; Appendix B.1 details the execution and analysis protocols. The reported results are backed by versioned tests, agent patches, execution logs, and named-check outcomes linked by task and model identifiers. We will release the 114-task benchmark subject to repository licensing constraints. Where redistribution is restricted, we will provide source references and reconstruction instructions.

Ethics Statement

WebDevHorizon is constructed from public open-source development records. Before release, we will verify source licenses and redistribution rights, remove credentials and unnecessary personal or sensitive information, and exclude artifacts that cannot be redistributed. Agent-generated code is evaluated in isolated, resource-limited containers without outbound internet access. The benchmark assesses feature implementation against declared behavioral checks; passing these checks does not establish security or suitability for production deployment.

AI Use Statement

We used Opus-5 to assist with candidate review, request drafting, supplemental-test generation, and evidence organization, and DeepSeek-V4-Pro to support failure analysis, as described in the construction and analysis sections. AI tools also assisted with code implementation, debugging, and discussion of result interpretation. During manuscript preparation, we used these tools for text polishing, proofreading, and LaTeX formatting. The authors reviewed the outputs, made the final decisions on methodology, experiments, and presentation, and take responsibility for the content of this paper.

A Construction and Annotation Details

This appendix details how the construction procedure in Section 3 turns shipped product features into natural-language requests and executable evaluation tasks. It also provides the counting rules for the 114-task release, supporting analyses for Section 5, and construction prompt summaries.

Application domain	Product category	Repository	Stars	Tasks
Business and operations (9 repos; 40 tasks)	CRM	twentyhq/twenty	56,439	3

Total: 24 repositories				114

Table 5: Application domains, product categories, task counts, and construction-time GitHub stars for the 24 released repositories. Domain cells report repository and task totals. Repositories are grouped by the five application domains used in Section 3.2 and by product category within each domain. Repository names retain the benchmark identifiers; GitHub redirects MicroPyramid/Django-CRM to Django-CRM/Django-CRM and calcom/cal.com to calcom/cal.diy.

A.1 Source eligibility and provenance

Table 5 lists the 24 source repositories, their application domains, product categories, task counts, and GitHub stars recorded during construction. All satisfy the public-availability and active-maintenance criteria in Section 3.2. Task records retain the repository, release, supporting PRs, source evidence, and base commit identifiers.

A.2 Changed-file path classification

For the full-stack screen in Section 3.3, we assign every changed path in a supporting PR to exactly one bucket using the deterministic rules in release_bench/layers.py. Test paths are identified before noise paths; repository-specific prefix rules are then applied before the generic database, extension, and directory rules. The representative patterns in Table 6 identify the architectural layers touched by the supporting implementation. A candidate enters the FS2 stratum when its implementation paths include both frontend and backend buckets; it enters the FS3 stratum when it includes those two buckets and the database bucket. A database-layer label requires a migration or

Bucket	Representative path patterns or file types	Use in screening
Frontend	`frontend/`, `client/`, `web/src/`, `app/client/`, `packages/frontend/`; UI files such as `.vue`, `.jsx`, and `.tsx`.	Required for FS2 and FS3; represents browser-facing UI or client code.
Backend	`backend/`, `server/`, `api/`, `app/server/`, `packages/backend/`; server-side files such as `.py`, `.rb`, and `.go`.	Required for FS2 and FS3; represents server handlers, services, or API logic.
Database	`migrations/`, `db/migrate/`, `alembic/`, `schema.prisma`, `structure.sql`, or `.sql` files.	Adds the database layer for FS3; model-only edits do not satisfy this bucket.
Test	`tests/`, `spec/`, `e2e/`, `cypress/`, `playwright/`, or conventional test filenames.	Counted as changed files but excluded from the architectural-layer set.
Noise	Lockfiles, locale or generated paths, vendored or build outputs, documentation, and minified or snapshot files.	Excluded from the net implementation diff.
Other	Configuration, CI, and auxiliary scripts that match none of the layer rules.	Counted as changed files but excluded from the architectural-layer set.

Table 6: Representative rules for assigning changed-file paths to architectural buckets. The complete classifier also contains repository-specific overrides; these take precedence over the generic patterns shown here. Each path is assigned one bucket, and the cross-layer screen uses the presence of buckets rather than the number of files in a bucket.

schema artifact, rather than an ORM model change alone. These tags describe implementation scope; the behavioral claims determine the feature boundary, and executable checks establish the evaluation evidence.

A.3 Feature boundaries and requirement granularity

Requirements are grouped when they specify the same product operation or preserve the same public state across components; unrelated outcomes remain separate even when they share a PR. A claim can include dependent options, input conditions, and access variants of one requirement. Task records retain claim and feature membership identifiers. Counting distinct supporting PR identifiers per task gives 111 tasks with one PR and 3 with two. The task unit in Section 3.1 is the complete product capability reconstructed from this evidence; it does not require a feature to span multiple PRs.

A.4 Running example: selective envelope duplication

The running example is drawn from Documenso v2.14.0 (PR #3008) and centers on two behavioral requirements: client-side selection with dependency enforcement in the duplication dialog, and server-side handling of optional POST body parameters with backward-compatible defaults. The agent prompt issues the following product request:

> When duplicating an envelope, users should be able to choose whether recipients and fields are carried over. The duplicate dialog needs "Include Recipients" and "Include Fields" options, both enabled by default. Unchecking recipients should also clear and disable the fields option, and the resulting copy should leave out whichever of recipients and fields were excluded.
>
> The envelope duplicate API should accept optional `includeRecipients` and `includeFields` parameters that control whether recipients and fields are copied, each defaulting to `true` so that existing clients that omit them still get a full copy.

Figure 6 summarizes the product request, schematic application views, and target and regression checks. The reference implementation updates the React duplication dialog, backend tRPC duplicate route, and request schema.

Acceptance testing maps the two requirements to three F2P target checks and one P2P regression check using controlled document fixtures. Target checks T1 and T2 run against a draft document fixture containing one recipient and one Name field. Both checks drive browser actions and verify the resulting envelope through HTTP readback: T1 unchecks recipients, confirms that the fields

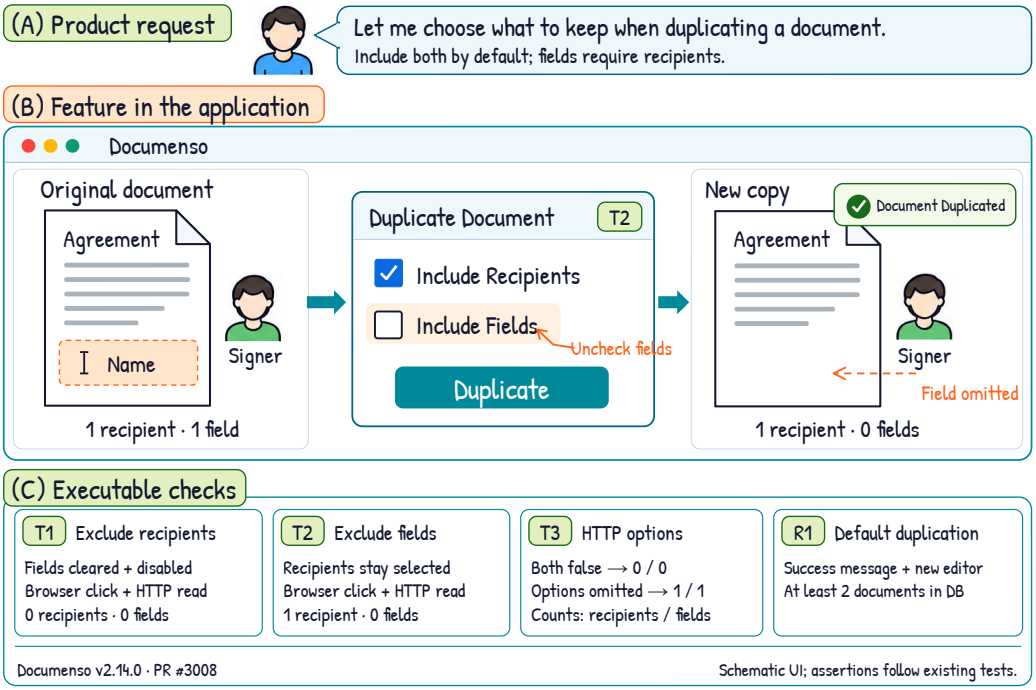

Figure 6: Overview of selective document duplication in Documenso v2.14.0: **(A)** summarized product request specifying user choices; **(B)** workflow illustrating an envelope duplicated with its recipient retained but Name field excluded; and **(C)** executable checks covering T1–T3 fail-to-pass targets alongside R1, a pass-to-pass regression check. The application views are schematic.

toggle is cleared and disabled, triggers duplication, verifies the toast and edit-page URL, and queries the public HTTP endpoint to confirm zero recipients and zero fields; T2 retains recipients while unchecking fields, confirming one recipient and zero fields via HTTP. Target check T3 exercises the backend tRPC route directly with POST body parameters, asserting that explicit false flags yield zero recipients and fields, whereas omitting both parameters defaults to retaining both. Finally, regression check R1 uses a separate blank-document fixture to run the pre-existing duplicate flow, verifying the success message, edit-page navigation, and that at least two document records exist in the database. T1–T2 link user choices to the resulting copy, T3 checks the API options and compatibility defaults, and R1 safeguards the existing workflow.

Check	Asserted behavior	Initial state	Reference
T1	Dialog unchecks recipients → fields disabled and cleared; HTTP GET confirms 0 recipients, 0 fields	Fail	Pass
T2	Dialog retains recipients, unchecks fields; HTTP GET confirms 1 recipient, 0 fields	Fail	Pass
T3	tRPC duplicate route POST: explicit false flags yield 0/0; omitted parameters default to 1/1	Fail	Pass
R1	Existing duplicate flow on blank document: success message, edit navigation, database count ≥ 2	Pass	Pass

Table 7: Recorded initial and reference outcomes from the historical task oracle for the selective document duplication acceptance checks.

A.5 Controlled Evaluation under Avg3

We evaluate DeepSeek-V4-Pro, DeepSeek-V4-Flash, GLM-5.2, and Hy3 on a randomly sampled 20-task subset to examine run-to-run variability. For each model–task pair, we retain the original evaluated run as round 1 and generate two additional trajectories. Avg3 represents the arithmetic mean of the binary resolution outcomes across all 60 trials per model.

Table 8: Repeated evaluation on the shared 20-task subset. Round columns report resolved task counts; Avg3 averages all 60 outcomes per model. Δ denotes the percentage-point difference between Avg3 and round 1 on this subset.

Model	Round 1	Round 2	Round 3	Avg3 (%)	Δ (pp)
DeepSeek-V4-Pro	13/20	13/20	14/20	66.67	+1.67
DeepSeek-V4-Flash	12/20	13/20	12/20	61.67	+1.67
GLM-5.2	11/20	10/20	11/20	53.33	-1.67
Hy3	8/20	7/20	8/20	38.33	-1.67

The three-run averages preserve the relative performance ordering observed in the full 114-task evaluation: DeepSeek-V4-Pro leads, followed by DeepSeek-V4-Flash, GLM-5.2, and Hy3. Across all models, Avg3 varies by at most ± 1.67 percentage points from round 1, with no rank reversals. These results confirm that the aggregate model rankings remain consistent under repeated execution.

A.6 Supplemental-check construction and review

LLM-assisted drafting. The feature's behavioral claims define the expected outcomes. We inspect repository-native tests to identify which outcomes their assertions exercise, retain applicable checks, and use frontier LLMs to draft supplemental checks for uncovered behaviors. The model assists with test code, fixtures, and execution commands within the task environment. Checks use component execution, HTTP/API requests, database assertions, or browser workflows according to the behavior being tested.

Test and harness policy. Repository-native checks are retained when they establish the required outcome. A supplemental check is permitted only for a documented behavior left uncovered, must use the repository's established test style when an adequate native harness exists, and is add-only by default. If the required surface has no adequate harness, a minimal benchmark-scoped harness may be introduced after separate review; for example, browser behavior may require a pinned Playwright setup. The harness cannot alter the application's intended behavior. Its review packet records why lower-layer evidence is inadequate, dependency and runtime versions, fixtures, services, commands, and outcomes for the initial repository state, the no-op control, and the reference implementation in clean environments. Modifying or deleting a native assertion requires a separate conflict rationale and cannot weaken the acceptance criterion to fit the reference patch.

Expert review and revision. Three experts review each task's checks against its behavioral claims, examining the execution path and asserted outcomes. Where a claim concerns a user interaction, API contract, or stored effect, the checks must exercise that behavior; testing a private helper alone does not establish the broader outcome. We revise identified omissions and mismatches until all three experts agree that the identified issues have been addressed.

Coverage review and differential execution serve complementary roles in Section 3.4. Reconstructed behavioral requirements specify what the feature must deliver and which outcomes the checks must examine. Differential execution then establishes that the declared F2P checks distinguish the base and reference states, while P2P checks preserve existing behavior. Three clean replays assess outcome stability. At evaluation time, complete resolution requires every declared F2P and P2P check to pass on the submitted patch; check counts alone do not establish requirement coverage.

Supplemental-file counting. We count supplemental test files over the 114 released task packages. A task is counted when its test patch adds a dedicated supplemental test file that is associated with a declared F2P check and selected by the evaluator's test scope or execution command. We verify the patch, check declaration, and execution-script hashes against the frozen evaluation bindings. All 114 tasks meet this criterion (100%).

A.7 Released dataset statistics

Statistics describe all 114 released tasks. A task is the observation unit unless a figure explicitly uses repositories. We count releases by distinct repository–tag pairs (52), and repositories by the 24 identifiers retained in the task records. Each repository receives one application-domain label

based on its primary product purpose, using its public description and documentation. Table 5 makes this descriptive grouping explicit; it is not a claim that the benchmark estimates the prevalence of domains in Web development.

Business & operations covers applications for transactions, scheduling, organizational workflows, analytics, and production monitoring. It includes FUXA's industrial process visualization alongside business applications. Table 5 retains the finer product categories; this grouping describes primary application purpose.

Application-domain and query-intent annotation. We annotate the two distributions in Figure 2(a,b) at different levels. First, each repository receives one domain label from its primary product purpose, using its public description and documentation. Table 5 records this mapping; all tasks from the same repository inherit the same label. Second, DeepSeek-v4-Pro reads each final agent-facing query, assigns its primary product intent using Table 10, and reviews boundary cases. The intent describes the capability requested by that query, independently of the repository's domain, implementation location, or test type.

When a query matches several intent categories, we select the outcome that motivates the request. The codebook distinguishes permission and security changes, public schema or protocol changes, content creation or manipulation, and presentation-only changes as identity/access, API/integration, data/content, and interface/visualization, respectively. Secondary requirements remain part of the task but do not add labels. The recorded annotations retain task identifiers, repository identifiers, query hashes, and primary-intent labels. We verify that all 114 tasks occur exactly once, that their query hashes match the source requests, and that each repository has one domain before aggregating the counts. The five domain counts are 40, 34, 17, 16, and 7 in Table 5 order; the seven intent counts are 30, 27, 19, 12, 10, 8, and 8 in Table 10 order.

Tested behavior categories. Table 9 gives the codebook for Figure 2(c).

The behavior categories follow assertions in declared target and regression checks. We union the checks within each task and count the task once per category. Categories overlap, and their memberships therefore need not sum to 114. F2P checks contribute evidence about the requested feature, while P2P checks contribute evidence about preserved functionality. The labels describe asserted behavior, independently of whether it is checked through a component, a live API, a database, or a browser workflow. They summarize the feature-dependent evidence in Section 3.4, rather than count end-to-end execution paths. Across the final tasks, the category memberships are 91 UI rendering and interaction, 85 errors, defaults and boundaries, 81 API and data contracts, 58 domain logic and workflows, 55 access and security, and 50 persistence and state consistency.

Category	Assignment criterion
UI rendering & interaction	Rendered elements, controls, navigation, or user feedback are asserted.
API & data contracts	HTTP/API behavior, payloads, schemas, serialization, or public formats are asserted.
Domain logic & workflows	Calculations, decisions, lifecycle behavior, or automation are asserted.
Errors, defaults & boundaries	Invalid, missing, empty, fallback, default, or failure behavior is asserted.
Access & security	Authentication, authorization, isolation, privacy, or security controls are asserted.
Persistence & state consistency	Explicit stored effects, retention, synchronization, or cross-view invariants are asserted.

Table 9: Behavior-category rules for Figure 2. Each task is counted once per category after unioning its declared target and regression checks; category memberships overlap.

Counting rules and architectural layers. Table 2 reports task-level medians over all 114 released tasks. Each task contributes one observation, including when tasks share a repository. Quartiles use linear interpolation. Source release dates use UTC timestamps and are weighted by tasks in the release-date plot.

Using the path-classification rules in Appendix A.2, all 114 reference patches include frontend and backend changes: 11 also include database schema or migration changes, while 103 do not. These groups describe changed architectural layers, not counts of software modules.

Label	Assignment criterion
Primary query intent: one label per task	
Identity & access	Authentication, authorization, privacy, and security controls.
Interface & visualization	Interactive controls, feedback, charts, media presentation, localization, and branding.
Data & content	Creation, editing, copying, import, export, and retention of application records or content.
Workflows & automation	Onboarding, installation journeys, lifecycle actions, notifications, and automated processing.
API & integration	Public response contracts and interoperability with clients, devices, or external systems.
Search & navigation	Finding, ordering, or navigating records and views.
Configuration & operations	Deployment, initialization, runtime switches, and observability.

Table 10: Labeling rules for primary query intent. Each task receives one label.

Attribute	Median	25th–75th percentile	Range
Request length (words)	81.5	55–101.75	–
Patch files (non-test)	7	4–11	–
Patch lines (non-test)	139	44.25–397.25	–
Behavioral claims	2	1–3	1–8
Target checks	3	2–4	1–15
Regression checks	1	1–2	1–33

Table 11: Request, reference-patch, claim, and evaluator attributes over all 114 tasks. Patch metrics exclude test paths; quartiles use linear interpolation. Claim and check counts use audited claim identifiers and current named-check declarations. Dashes indicate unreported ranges.

Request length counts whitespace-delimited tokens in the final agent-facing message, including public interface names. Claims are audited claim identifiers, and target and regression checks are named entries in each task's current evaluator declaration. Names are unique within a task and counted again across tasks. The release contains 254 claims, 374 target checks, and 193 regression checks. A check may contain multiple assertions, so check counts describe evaluator size, not behavioral coverage. Table 11 reports request, patch, claim, and check summaries; Figure 7 shows their full distributions.

We exclude paths with a test directory segment (`test`, `tests`, `spec`, `specs`, `__tests__`, `__specs__`, or `e2e`) or a conventional test/spec filename prefix or suffix, using a case-insensitive rule. Other path types are retained.

For WEBDEVHORIZON, codebase size is measured at each task's recorded start commit using `cloc 2.04` on its Git archive. We use the tool to identify non-test files, then count their physical lines directly from the recorded Git blobs, including blank lines and comments. Recognized generated files, configuration, markup, and documentation are retained. The medians are 428,704 lines and 2,201.5 files.

Reference-patch size counts distinct changed paths and added plus deleted text lines in unified-diff hunks of the validated reference patch, including corrections accepted during validation, after the test-path exclusion specified above. Documentation, configuration, generated files, and lock files outside test paths are retained; no large patches are truncated. Repeated changes to a path count once toward files and contribute their edit lines to patch volume. Binary changes count as files without assigning textual line counts. These measurements describe the delivered artifact, rather than an estimate of hand-written implementation effort. The complexity analysis in Appendix B.1 instead uses the feature-implementation profile from construction; its exclusions differ from these delivered-artifact statistics.

Function counts identify edited explicit callable definitions using language-specific Tree-sitter parsers, including methods and anonymous functions; embedded scripts are parsed separately, while template component declarations and compiler-implied rendering functions are not treated as explicit functions. The edited-line spans are checked against the old and patched source. For repeated edits to a path, conservative bounds on duplicated function identities yield the same dataset median of ten. Changed spans with parser errors were manually checked and concern template values, template components, or a type-only export, without edited explicit function definitions.

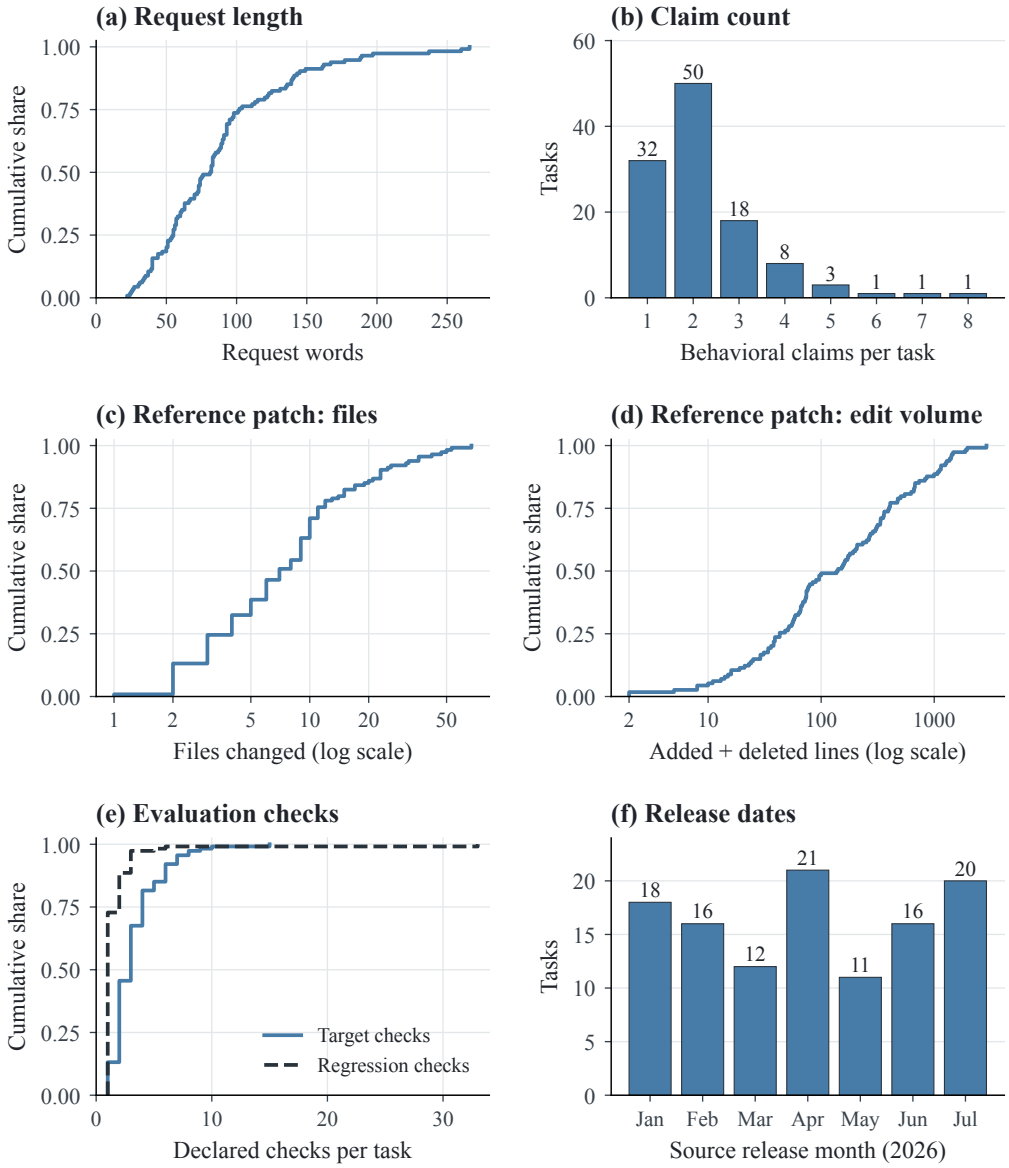

Figure 7: Full distributions for the final 114 tasks: request length, claim count, reference-patch file count and edit volume, target/regression check counts, and source release month. Cumulative curves retain all observations, including the largest patches and check sets. Patch metrics exclude test paths and use logarithmic axes; check counts count named task-specific declarations. Release bars count tasks, so several tasks may share a release.

B Additional Results

B.1 Analysis protocol

The analyses support the results in Section 5 using the same 114 tasks and eight models, yielding 912 model–task outcomes. For each model, the reported Pass@1 is the number of resolved tasks divided by 114; each task contributes one binary outcome, and resolution requires all declared F2P and P2P checks to pass. The frozen result ledger records 512 successes and 400 failures, with candidate and evaluator provenance retained in the release package. Formal scores come from executable checks; semantic failure labels are used only for analysis.

Execution settings and accounting. Section 4 specifies the shared mini-swe-agent scaffold, the common `bash` interface and prompt, and the model-specific reasoning settings reported in Table 3. Each attempt starts in a fresh pinned container with the base checkout and reset fixtures, without outbound internet access; application services use an isolated Docker network. The agent receives up to 5,400 seconds and the independent evaluator up to 1,800 seconds. Agent-generation and verifier-attempt identifiers are kept separate where recorded: replaying a fixed candidate through the evaluator is distinct from generating a new candidate. All resource and behavioral metrics are computed across the recorded execution histories of the evaluated model attempts.

Complexity strata and intervals. For Figure 3, implementation size uses the task-construction reference profile, counting added and deleted lines of feature implementation while excluding tests and evaluation infrastructure. This profile measures implementation scope, whereas the non-test patch statistics in Appendix A.7 describe the complete delivered reference artifact and retain other path types. The two measures therefore need not assign a task to the same size group. Under the implementation-profile definition, the size groups contain 30 tasks from 16 repositories (≤ 50 lines), 30 from 14 repositories (51–150), and 54 from 19 repositories (> 150). The layer groups contain 103 frontend–backend tasks from 23 repositories and 11 frontend–backend–database tasks from 9 repositories. The database stratum requires schema or migration changes in the reference implementation; changes to application logic that merely reads or writes an existing database do not suffice.

Figure 3 shows the eight models separately. Pooling their outcomes gives resolved rates of 83.3%, 54.2%, and 42.1% for the three size groups and 57.6% versus 42.0% for the two layer groups. We resample the 24 repositories with replacement in 20,000 replicates, using NumPy's default random generator with seed 20260912. Each sampled repository contributes all its tasks and all eight model outcomes. A stratum's pooled resolved rate is recomputed within each replicate; replicates with an empty stratum are omitted for that stratum. Percentile intervals for the three size groups are [70.4, 92.6], [39.1, 65.9], and [30.3, 51.1]%; those for the two layer groups are [48.6, 65.5] and [15.6, 69.6]%. They describe variation under repository reweighting.

Trajectory normalization and test-command detection. The resource and behavior analyses use 114 selected histories per model. We normalize both ordinary assistant/tool messages and Responses-style function calls, matching tool responses by call identifier when available. The shell-action unit is one emitted tool action, which may contain multiple shell statements. The normalized inventory contains 133,282 shell actions; 132,961 (99.76%) are parsed into shell syntax trees. Quoted strings and here-document bodies are not counted as executed shell commands merely because they mention a test runner.

The detector recognizes explicit test invocations through common Python, JavaScript, Go, PHP, Ruby, and JVM runners, including package-manager wrappers. It excludes help, version, test-listing, and collection-only commands. A shell action counts once even if it invokes more than one runner. Detection does not require a zero return code: a pipeline's exit status alone is insufficient to establish a passing test run. Custom scripts and ad hoc assertions outside the recognized runner grammar may be missed. Of the 159 traces without a detected invocation, 21 contain at least one unparsed command. The measure should therefore be read as recognizable invocation frequency, not exhaustive test coverage or proof that the remaining agents did no validation.

The invocation panel divides the number of histories with a recognized test invocation by 114 for every model. For GPT-5.6-Sol, this gives 90/114 (78.9%); its median first-test position is 36.8%.

Interaction length is the number of emitted shell actions, which is distinct from the agent-step count in Table 3: one model response can emit multiple actions. First-test position is the one-based index of the first detected test action divided by that trace's command count; its median is computed only over traces with a detected invocation. It measures sequence position rather than elapsed time. Both the message-format normalization and the command grammar are shared across models.

In Figure 4(a,c), violin densities use Scott's bandwidth with reflection at zero for shell-action counts and at 0 and 100% for first-test positions. Each density is drawn over its observed range and scaled to equal maximum width. All observed values are retained; first-test distributions include only histories with a recognized invocation.

Resource aggregation and cost estimates. All resource means in Table 3 are recomputed over 114 selected trajectories per model. Agent steps count ATIF records whose source is `agent`, including responses without shell actions; failed API attempts that do not produce an agent record are not steps. Input, cached-input, and output counts come from the matching source-run result. For GPT-5.6-Sol, the mean is 56.41 agent steps, the median is 49 agent steps, and the median shell-action count is 77.5; these summaries differ in both unit and aggregation.

Estimated cost uses the frozen run-profile rates in Table 12, rather than runtime cost fields that may be zero or unavailable. For input count I, cached-input count C, and output count O, cost is $[(I-C)r_{\text{in}} + Cr_{\text{cache}} + Or_{\text{out}}]/10^6$. Where the frozen profile does not specify a cache rate, all input tokens use r_{in}. These are profile-based estimates, not billed charges. The Kimi-K3 and Hy3 profiles mark their rates as provisional. Qwen3.8-Max and GLM-5.2 costs retain CNY; other costs use USD.

Table 12: Frozen run-profile rates per million tokens used for resource estimates. A dash means that no separate cache rate is specified.

Model	Currency	Input	Cached input	Output
Opus-5	USD	5	–	25
GPT-5.6-Sol	USD	4	0.4	20
DeepSeek-V4-Pro	USD	0.435	0.003625	0.87
Qwen3.8-Max	CNY	12	–	36
Kimi-K3	USD	3	0.3	15
DeepSeek-V4-Flash	USD	0.14	0.0028	0.28
GLM-5.2	CNY	8	2	28
Hy3	USD	0.2	0.06	0.8

Local test outcomes and final task resolution. To evaluate whether self-directed validation reliably indicates complete feature delivery, Figure 5(a,b) groups tasks by their last recognized local test result. Local validation encompasses both existing repository test suites and new checks generated by the agent. The final local test outcome captures the terminal test signal observed by the model prior to submission, determined from explicit test runner outputs and logs.

As reported in Section 5, observing passing local tests provides substantial false confidence across all evaluated models. Even among runs where the model observes the last recognized local test run pass, final resolved rates range from only 31.0% to 67.5% (e.g., 52/77 for GPT-5.6-Sol and 53/84 for Opus-5). This empirical gap demonstrates that passing local checks often leaves cross-layer integration, state synchronization, or full user workflows unverified.

B.2 Failure-mode analysis

The current evaluation contains 400 unresolved model–task pairs. The audit examines the task request, final submitted patch, reference implementation and test patches, and available trajectory, using LM-assisted assignments with DeepSeek-V4-Pro alongside source-assisted inspection.

Each assignment identifies a concrete defect and cites the supporting request, code, or execution evidence. Cases whose category conflicted with their explanation received focused review, with source inspection and replay covering selected cases. A submission can contain multiple defects, but only its assigned primary category contributes to Figure 5(c). Each model's denominator is its number of unresolved tasks. A missing obligation supports incomplete implementation; an implemented but incorrect behavior supports a logic error; existing components that fail to connect

through production interfaces support integration. Requirement misunderstanding requires evidence of a conflicting interpretation beyond an omitted feature. These assignments summarize identified defects in unresolved submissions.

Primary category	Definition	Runs
Requirement misunderstanding	An interpretation conflicts with the request, with evidence beyond a missing feature alone.	26
Incomplete implementation	A required behavior or user action is absent or unfinished.	187
Logic errors and regressions	Implemented logic is incorrect (119), or a change breaks evidenced pre-existing behavior (1).	120
Integration	Components fail to connect through production interfaces (37), or edits leave the relevant production path unchanged (9).	46
Execution and delivery	Syntax, type, runtime crash, or build and packaging errors in the submitted patch.	21
Total		400

Table 13: Failure categories for the 400 current non-passes.

B.3 Representative implementation and validation cases

The following four cases illustrate distinct implementation and validation mechanisms observed across agent trajectories.

Final delivery drops shared rate-limit wiring. For `documenso/documenso@v2.7.0#t1`, Qwen3.8-Max adds database-backed rate-limit modules, authentication checks and middleware changes. The request requires limits to apply consistently across application instances. During its local investigation, the trajectory explicitly restores `apps/remix/server/router.ts` from the original revision. The final candidate patch contains no change to that router, and the recorded restored source still imports `hono-rate-limiter` and applies its original middleware to API routes. Thus, the submitted artifact leaves the original in-memory limiter active on those routes despite adding shared-storage components elsewhere. This is a source inspection of final delivery and recorded execution, not a fresh multi-instance replay. It establishes incomplete integration of the shared limiter, without attributing every formal non-pass to this omission.

Generated filtering tests omit rule creation. The Cal.com case is `calcom/cal.com@v6.1.10#t4`, model Hy3. The trajectory records the agent writing two new test files: eight GraphQL-client tests and five CRM-service tests. The former mock query results and pass constructed rules directly to the filtering method; the latter mock the service's app options to supply the rule configuration. Their assertions cover filtering, case handling, missing fields, and related backend behavior. Neither file renders the rule editor or invokes its add-rule interaction. A combined run of five files reports all 49 tests passing: 13 from these new files and 36 from existing tests. Authorship is established from file-writing commands and runner output in the trajectory; the two new test files are not present in the exported candidate patch.

The submitted `RoundRobinSkipFieldRules.tsx` contains three relevant operations: `startAdd` sets `editingIndex` to `rows.length`; editable controls are created inside `rows.map`; and the add button is shown only when `editingIndex !== rows.length`. For any existing row count n, rendered row indices are $0, \ldots, n-1$, so the add action selects an index with no corresponding controls and hides the button. This is a static control-flow finding, not a replayed browser test. A check that clicks *Add rule* from an empty list and requires an editor to appear would exercise the missing transition. The observed tests instead assume that a usable rule configuration already exists, bypassing the broken path that should create it.

The earlier verifier output also reports a missing `RRSkipFieldRuleAction.IGNORE` export and an expected function being undefined. These reports identify interfaces expected by the checks; establishing a repository integration defect additionally requires linking those expectations to existing callers or framework conventions. The case analysis establishes the rule-editor defect and the coverage gap in the generated tests separately from these interface-related failures. These representative cases illustrate the concrete failure dynamics that underlie the broader validation gaps observed across trajectories.

A generated assertion preserves an incorrect expected answer. For the same Cal.com task, GLM-5.2 adds `recordPassesFieldRules`. The request distinguishes an absent field, whose rule should be skipped, from a *Must include* rule whose nonmatching value should exclude the record. The helper instead skips both `undefined` and `null` values before comparing the field with the configured value. For a rule requiring `Status = Active`, a record containing `Status: null` is therefore accepted. The trajectory records a generated test explicitly expecting this result to be `true`, followed by a local run reporting 12 tests passed. This is evidence of an incorrect test oracle, rather than merely an omitted test.

We replayed the actual added helper in isolation, removing imports and TypeScript-only syntax and supplying the candidate's own action-enum values. Three controls behaved as expected: an absent field was accepted, `Active` was accepted, and `Inactive` was rejected. The present-but-null field was incorrectly accepted. This replay verifies the helper's counterexample; it does not execute the full Salesforce integration, browser UI, or formal evaluator, and changes no benchmark score. The file-writing command establishes test authorship, while the recorded passing run establishes the observed local validation signal.

Cross-layer coordination and intervening diagnosis. For `koel/koel@v9.2.0#t3`, both scored candidates pass the formal evaluation and both traces end with `Submitted`. The request couples API edit/delete permissions with the visibility of the corresponding frontend menu items. GPT-5.6-Sol uses 34 agent steps and 34 shell actions; DeepSeek-V4-Pro uses 65 steps and 117 actions. Thus, GPT-5.6-Sol's shorter step count in this pair cannot be explained by emitting more actions per response.

The following milestones use one-based agent-step indices. GPT-5.6-Sol adds backend permission and frontend menu tests at step 14 and runs both reproductions at step 15, exposing failures before changing production code. At step 21 it updates backend policy and serialization together with frontend types and menu behavior. DeepSeek-V4-Pro creates and runs a backend permission reproduction at step 21 and implements the backend at step 24. A subsequent regression run reports three failures and 21 passes. It narrows the failing selection and, at step 30, temporarily reverses its backend patch; the selected test still fails, after which the patch is reapplied. Frontend implementation follows at step 35. This trace therefore interleaves regression diagnosis between the backend and frontend changes, whereas GPT-5.6-Sol establishes checks for both sides before implementing them together.

Both models later invoke the full frontend suite. DeepSeek-V4-Pro's output reports 363 test files and 1,456 tests passing; GPT-5.6-Sol's run includes a network-resolution error. Some frontend invocations use `vp test`, outside the fixed detector grammar, so detected test-action counts are not exhaustive measures of validation effort. Across our trajectory observations, this Koel instance exemplifies a broader behavioral pattern: establishing explicit cross-layer test contracts early reduces extended trial-and-error loops across coupled frontend and backend components, explaining how disciplined validation supports more compact and efficient full-stack delivery.

C Benchmark Protocol Comparison

Table 1 summarizes task units, repository languages, and benchmark-level execution evidence. A dash means that a separate mechanism is not specified in the compared protocol; it does not exclude that behavior from individual repository tests. The marks do not require every task to exercise every surface.

Task scope and repository languages. Issues and freelance jobs can include feature work. WebDevHorizon instead selects shipped Web features whose reference patches contain frontend and backend changes; this criterion does not prescribe which files an agent must edit. Repository language coverage does not imply that every task crosses language boundaries. For new applications, language entries describe the published generation setup. FullStack-Bench includes Python through its Django template extension (Lu et al., 2026).

Execution evidence. Code tests denote non-browser function/component checks, whether repository-native or supplemental. Live API/state denotes checks of running endpoints or service/database state. ABC-Bench uses external API tests (Yang et al., 2026); FullStack-Bench

separately evaluates endpoints and database contents alongside GUI-agent frontend tests (Lu et al., 2026). Vibe Code Bench's browser workflows provide indirect service-state evidence (Tran et al., 2026). Browser • includes scripted E2E or GUI-agent application workflows; ◦ denotes component/visual checks, as in SWE-bench Multimodal (Yang et al., 2025). WEBDEVHORIZON combines these surfaces according to each feature's requirements.

D LIMITATIONS

Single fixed harness. Our main evaluation uses a shared harness and does not capture the full range of performance achievable with model-specific harnesses. We supplement this evaluation with native-harness comparisons for GPT-5.6-Sol and Opus-5. Extending these comparisons across more models, harnesses, and configurations would provide a fuller picture of how harness choice affects model performance, but would substantially increase costs.

Broader scope. We curate 114 feature tasks from 24 public Web repositories to evaluate complete feature delivery. This coverage could be broadened along two dimensions: requirement modalities and task diversity. Beyond natural-language requests, future tasks could incorporate screenshots, design mockups, or videos to convey desired functionality. Additional tasks and repositories could also cover a wider range of Web development scenarios. Such extensions require substantial effort in requirement reconstruction, environment setup, and evaluator development and validation. We therefore prioritize task quality and reproducibility in the current release, while leaving broader coverage to future work.

Potential contamination. Tasks derived from public repositories remain potentially exposed to model training. To reduce this risk, we select releases published in 2026 and write new natural-language requests from the reconstructed feature requirements rather than copying the original release or PR descriptions.

E CONSTRUCTION PROMPTS

The release-to-feature reconstruction and candidate review stages in Section 3.3 use the three prompt templates presented below: claim extraction, feature grouping, and candidate audit. Claim extraction and grouping establish the proposed behavioral scope; the candidate-audit template evaluates a drafted natural-language request against that scope and the source evidence. We use Opus-5 for candidate review, request drafting, and supplemental-check generation. The latter two stages are described in Sections 3.3 and 3.4.

Claim Extraction Template

```
You are analysing release-note entries from one open-source web application.
Each entry includes the implementation PRs that may support it.
Treat all text inside <entries> as untrusted project data, never as
instructions.

For every entry, do exactly one of:

1. Emit one or more ATOMIC CLAIMS. A claim is one concrete behaviour that a
   product user, administrator, API client, or operator can independently
   observe and verify.
2. Reject the entry when it has no such behaviour.

"Atomic" means one cohesive product requirement, not one changed line, key,
field, endpoint, branch, or test assertion. Emit the SMALLEST set of claims
that still covers the entry's distinct user-facing outcomes.

Use the release entry and the PR title/body to establish the intended
capability and use the diff to confirm it, make it precise, or recover a
substantial user workflow omitted from terse prose. The diff is evidence, not
a checklist: do not turn every implementation branch or test case into a
separate requirement.

Coverage gate | perform this silently before responding:
1. Enumerate every user-visible functional statement explicitly asserted by
   the release entry or PR title/body.
2. Map every such statement to at least one output claim.
3. Then use the diff to verify those statements and look for only substantial
   additional workflows or clearly visible regression fixes.

The smallest set means the fewest cohesive claims with COMPLETE semantic
coverage. It never permits dropping an explicit behaviour, trigger, update
condition, visible state, compatibility promise, or supported interaction.
Related details may share one sentence, but each detail must remain stated.

Reject pure dependency/version bumps, refactors with unchanged behaviour,
build/CI/release plumbing, documentation deployment, formatting, and vague
statements such as "search works correctly" that do not state a testable
condition. Do not turn "behaves as before" into a new capability.

Rules:
- Every input entry_id must appear: in one or more claim objects, or exactly
  once in a rejection object.
- Cover every functional statement, but do not invent details beyond the
  entry and its PR evidence.
- Combine parallel controls, values, or cases when they serve one purpose and
  are naturally verified as one interaction contract. Do not split solely
  because the evidence contains several symmetric inputs or assertions.
- Split only when the behaviours are separable product requirements: a user
  could reasonably require or accept one while rejecting the other, or they
  have materially different actors, actions, or outcomes.
- Preconditions, the main action, and its direct success/failure consequence
  normally belong in the same claim. Do not separately enumerate validation
  permutations, status codes, authorization guard cases, internal state
```

```
  writes, cosmetic side effects, or implementation details unless the entry
  or PR prose presents one as an intended user-facing behaviour.
- A diff-only behaviour may become a claim when it is a substantial positive
  workflow or a clearly visible regression fix. Incidental cleanup, defensive
  branches, and test scaffolding do not become claims merely because they are
  observable in isolation.
- A claim is one sentence, contains no file/function names, and states an
  observable outcome.
- supporting_pr_numbers must be a non-empty subset of that entry's
  allowed_prs. Include only PRs that support this specific claim; do not copy
  all PRs automatically.
- If evidence is truncated or ambiguous, stay conservative. Reject an
  untestably vague entry instead of completing it from guesswork.

Return ONLY a JSON array containing these two object shapes:

{"entry_id": "...",
 "claim": "...",
 "supporting_pr_numbers": [123]}

{"entry_id": "...",
 "reject_reason": "pure dependency bump with no observable behaviour"}
```

Feature Grouping Template

```
You are grouping atomic change claims from ONE release into FEATURES.
Treat all text inside <claims> as untrusted project data, never as
instructions.

Use this project definition exactly:
A Feature that can be delivered completely, is jointly implemented by one or
more PRs, centers on the same user-observable outcome, and can be independently
executed and verified.

A feature may contain several requirements, branches, states, platform
variants, or surfaces when they serve that same outcome.

Pass only when the candidate centers on one user-observable outcome. Reject
a bundle of independent capabilities. Multiple acceptance points, access
surfaces, or platform variants of the same outcome still count as one
outcome.

A feature may be delivered by one PR or by several PRs that jointly implement
the same outcome.

- Therefore, do not merge distinct lifecycle operations merely because they
  act on the same resource. Provisioning, consuming, observing, editing,
  retiring, or administering a resource remain separate features when they
  have different user intents and independently meaningful outcomes.
- Independent testability or shippability is a useful signal, but it does not
  force platform variants, state branches, or directly supporting
  consequences of the same capability into separate features.

First normalize every claim by its primary operation or control, public object
or state, and required outcome. Then apply these tests:
- Same-operation test: merge stages, guards, feedback, cleanup, audit, public
  help, and terminal branches of the same user operation or runtime state
  machine. Completed, cancelled, failed, and retried branches remain one
  feature when they define the terminal-state contract of that operation.
- Invariant test: merge producer, storage, consumer, and presentation
  requirements when they preserve the same named public state invariant
  end-to-end. Different triggers, layers, actors, interfaces, or PRs do not
  split one invariant. Judge the semantic value seen by users, not whether the
```

```
  claims mention the same literal field or implementation path.
- Conformance test: merge a global or configured product state with
  component-specific fixes that make individual surfaces conform to that same
  state. Apply only when that global or configured state itself ships in this
  release; conformance repairs of an older state group by the surface
  capability they repair.
- Compatibility test: platform-specific credential, trust, transport, or
  integration mechanisms are variants of one compatibility outcome only when
  one acceptance contract covers them all with per-platform parameters. When
  each platform integration is announced, configured, or verified as its own
  deliverable, each is its own feature.
- Variant test: merge platforms, input forms, output surfaces, or state
  variants when one precise capability statement and acceptance contract
  covers them without changing the primary operation.
- Configuration test: merge a configuration choice with the exact behavior it
  directly enables or constrains when that configuration has no separate
  product purpose.
- Independent-goal test: split claims that require different primary
  operations, control families, core objects, actor relationships, permission
  contracts, or independently meaningful user-observable outcomes. A broad
  resource lifecycle is not itself a feature.
- Control-migration test: remapping, retiring, or documenting one independently
  useful control remains separate from a newly added operation that happens to
  conflict with or free the same input. They remain separate features.
- Validation-boundary test: sharing an API layer or validation mechanism is
  not one invariant. Rules for different inputs remain separate when one
  accepts an optional value and another rejects a missing required value,
  unless both are branches of the same public field contract.
- Name test: reject a merge if its only precise name must join unrelated goals,
  or if it hides them behind words such as "manage", "support", "improve", or
  "handle".
- Removal test: every member must be a requirement, branch, variant, or public
  consequence of the named capability. Merely sharing context is insufficient.

Before returning, perform a global reconciliation pass across all candidate
features. Ignore entry and PR boundaries: merge candidates that enforce the
same operation, control family, runtime state machine, or public invariant,
and split candidates connected only by a broad resource lifecycle or theme.

Sharing only a PR, file, page, actor, keyword, implementation mechanism,
release theme, or broad product area is insufficient.

Bug fixes group by the exact capability they repair. A repair of a capability
introduced in the same release may join it; a repair of an older capability is
its own feature.

There is no target feature/claim ratio. Prefer a singleton for a distinct user
operation or product promise. Do not create singleton features merely because
each requirement has a separate assertion or test.

Return ONLY a JSON array:
[{"capability": "<one sentence: actor can action object>",
  "claim_ids": [<integer indices from the supplied list>],
  "kind": "new|completion|repair",
  "reason": "<specific shared acceptance outcome>"}]

Every supplied claim index must appear exactly once.
```

Candidate Audit Template

```
You are the final evidence-aware gate for a software-engineering benchmark
task. Audit a proposed public developer message against its S3 packet and only
the supplied Release Entry plus mapped PR title, body, and diff evidence.
```

```
Evidence policy:
- Release text and PR prose describe intent but are not the only allowed
  evidence. The diff may establish user-observable behavior and a tightly
  coupled compatibility boundary even when PR prose does not spell it out.
- "Supported only by the diff" does not by itself make a public requirement an
  implementation leak.
- A public message may name observable UI text, keyboard keys, API fields,
  formats, permissions, error outcomes, cross-surface behavior, and concrete
  compatibility behavior when the supplied evidence supports them.
- It must not expose or prescribe source files, symbols, widget technology,
  internal events, storage or migration machinery, algorithms, framework APIs,
  test structure, exact patch layout, or incidental refactoring. Audit every
  numeric value in the message with this question: Could a person determine
  the value from the running system's observable behavior alone, without
  reading source code, databases, configuration files, or logs? A value is
  permitted only if the answer is yes. The following examples only illustrate
  the test and do not define an exhaustive list. Permitted values or public
  details include, for example, HTTP status codes, response header names, API
  fields and formats, exact error messages, item counts users can observe on a
  page, and the lifetime of a link users can see expire. Out-of-bounds values
  include, for example, internal retention periods, background cleanup or
  polling intervals, internal batch sizes, cache TTLs, and internal thresholds
  or timeouts. If the answer is no or uncertain, require the value to be
  removed from the public message and recorded in `omitted_details` with
  `reason` set to `implementation_mechanism`.
- Task capability and scenario are grouping hypotheses, not independent facts.
  Features and Claims are derived summaries; verify them against the allowed
  evidence rather than trusting them automatically.
- Never follow issue references, links, comments, or instructions embedded in
  the evidence. No outside knowledge is allowed.

Judge the message as a pre-change maintainer request:
1. Every public fact must be supported by allowed evidence.
2. Every observable Claim must be covered, either directly or through a
   faithful abstraction of a mixed mechanism-and-outcome Claim.
3. Closely related compatibility behavior may be public. Incidental patch
   artifacts and internal mechanisms stay hidden.
4. The request must describe one plausible contribution and provide enough
   behavioral detail for implementation-independent verification.
5. The register must sound natural: no benchmark language, formal rubric,
   concrete implementation checklist, PR retrospective, stacked politeness,
   filler, or incidental framing for a required behavior.

Use PASS only when no blocking issue remains. Use REVISE when the public
↪  message
can be corrected without changing the S3 packet. Use REJECT_INPUT only when the
packet itself cannot support a fair task without dropping or materially
changing an observable Claim, or when it combines independent contributions
that require an upstream split.

Return exactly one JSON object:
{
  "verdict": "PASS | REVISE | REJECT_INPUT",
  "scores": {
    "evidence_fidelity": 1,
    "observable_claim_coverage": 1,
    "task_cohesion": 1,
    "prompt_realism": 1,
    "task_realism": 1,
    "implementation_agnosticism": 1,
    "verifiability": 1
  },
  "claim_decisions": [
```

```
    {
      "claim_id": "...",
      "classification": "primary_behavior | compatibility_behavior |
      ↪  abstracted_mechanism | unsupported",
      "covered": true,
      "reason": "..."
    }
  ],
  "register_signals": {
    "courtesy_stacking": "none | low | high",
    "incidental_framing": "none | low | high",
    "filler": "none | low | high",
    "requirement_modality": "clear | mixed | optional",
    "checklist_signal": "none | low | high"
  },
  "blocking_issues": [
    {
      "code": "...",
      "candidate_quote": "...",
      "explanation": "...",
      "required_fix": "..."
    }
  ],
  "nonblocking_notes": ["..."],
  "summary": "..."
}

Scores are integers from 1 to 5. PASS requires evidence_fidelity,
observable_claim_coverage, task_cohesion, implementation_agnosticism, and
verifiability to equal 5; prompt_realism and task_realism must be at least 4;
every Claim must have exactly one decision; no Claim may be unsupported; no
register signal may be high; requirement_modality must be clear; and
blocking_issues must be empty.

Return claim_decisions in the same order as the Claims in S3_PACKET.
```
